Toward Better Understanding of Protein Secondary Structure: Extracting Prediction Rules

Minh N. Nguyen, Jacek M. Zurada, and
Jagath C. Rajapakse

Abstract—Although numerous computational techniques have been applied to predict protein secondary structure (PSS), only limited studies have dealt with discovery of logic rules underlying the prediction itself. Such rules offer interesting links between the prediction model and the underlying biology. In addition, they enhance interpretability of PSS prediction by providing a degree of transparency to the predicting model usually regarded as a black box. In this paper, we explore the generation and use of C4.5 decision trees to extract relevant rules from PSS predictions modeled with two-stage support vector machines (TS-SVM). The proposed rules were derived on the RS126 data set of 126 nonhomologous globular proteins and on the PSIPRED data set of 1,923 protein sequences. Our approach has produced sets of comprehensible, and often interpretable, rules underlying the PSS predictions. Moreover, many of the rules seem to be strongly supported by biological evidence. Further, our approach resulted in good prediction accuracy, few and usually compact rules, and rules that are generally of higher confidence levels than those generated by other rule extraction techniques.

Index Terms—Protein structure, secondary structure prediction, support vector machines, multiclass SVM, C4.5 decision trees, rule extraction.

◆

1 INTRODUCTION

INFORMATION on secondary structures of amino acid residues in proteins provides valuable clues for the prediction of their three-dimensional (3D) structure and function. Knowledge of a protein's structure, in turn, contributes to our understanding of the functions of the protein and is vital to many aspects of living organisms such as those of enzymes, hormones, and structural material, etc. It also helps in designing new drugs for combating disease. Hence, prediction of 3D structure of a protein from its amino acid sequence has become one of the major goals of bioinformatics.

Unfortunately, the protein structure prediction problem is a combinatorial optimization problem, and hence, it has so far eluded an effective solution because of the exponential number of potential solutions. One of the current approaches is to first predict protein secondary structure (PSS) assuming a linear representation of the full knowledge of the 3D structure, and to use it to predict the 3D structure. The goal of secondary structure prediction is to assign a pattern of residues in amino acid sequences to a class of protein secondary structure elements most often labeled as an α-helix (a), β-strand (β), or coil (ζ), the remaining type.

Many computational techniques have been proposed in the literature to deal with the PSS prediction problem. The statistical methods are mostly based on the likelihood of each amino acid

sequence being one of three types of secondary structures [1], [2], [3]. Neural networks use residues in a local neighborhood as inputs and compute an arbitrary nonlinear mapping [4], [5], [6], [7]. The Bayesian approach provides a framework to account for nonlocal interactions among amino acid residues [3], where the inferences are based on the generalized probability distributions incorporating prior probabilities of segments of secondary structure elements. The consensus approaches combine different classifiers in parallel to achieve a single superior predictor. Cuff and Barton employed a majority voting scheme to combine predictions from different techniques [8]. More complex approaches for combining different methods based on neural networks and linear discrimination have also been studied [9]. Sen et al. proposed a consensus algorithm for protein secondary structure prediction by combining two complementary methods: fragment database mining (FDM) was used to exploit the Protein Data Bank structures and the GOR V based on information theory and Bayesian statistics [10]. Recently, Meiler and Baker proposed using the information of 3D structure and PSI-BLAST [11] profiles as inputs to a neural network [12]. Support Vector Machines (SVM) have been applied to PSS prediction, in combination with several binary classifiers [13].

The accuracy of the single-stage approaches to PSS prediction, however, has been found insufficient. Rost and Sander proposed the PHD approach using Multilayer Perceptrons (MLP) in cascade, with the second layer of MLP improving the accuracy of the prediction by capturing the contextual relations among the secondary structures at the output of the first layer [4]. We proposed a two-stage SVM (TS-SVM) for the prediction of PSS [14], of relative solvent accessibility [15], and of accessible surface area of amino acids [16], all with inputs from PSI-BLAST profiles. These techniques are able to incorporate useful information from multiple sequence alignments or PSI-BLAST profiles and contextual information among secondary structures in the prediction scheme.

Despite the success of many computational approaches, not much research has been done to discover what underlying general patterns of amino acid sequences are associated with specific secondary structure elements. Recently, He et al. proposed a rule extraction method for PSS prediction by combining SVM and decision trees [17]. The method uses one-stage of binary SVM, which is unable to capture contextual relationships among the secondary structures and cannot assign directly a pattern of amino acid sequences to a class of PSS outputs with sufficient accuracy.

To alleviate this shortcoming, we propose combining the PSS predictions from the TS-SVM with C4.5 decision trees to extract useful rules possibly governing PSS prediction. This not only increases the accuracy of prediction by decision trees or SVM along with decision trees, but it also renders a set of PSS prediction rules, which are more confident and more evident biologically as compared to rules reported so far. These rules describe amino acid patterns that are likely to produce specific secondary structures in a particular context. The rules can therefore imply protein structures likely to be produced by short segments of amino acids in a specific context, and may be useful in guiding biological experiments for determining protein structures, or, inversely, for inferring amino acid patterns from secondary protein structures.

The input to the TS-SVM is based on the position-specific scoring matrices generated by PSI-BLAST profiles of the input amino acid sequence. We use the output of TS-SVM to generate PSS prediction rules by C4.5 decision trees. We extracted three sets of rules for PSS prediction based on whether the prediction is purely on amino acid patterns, or it uses structural types of residues in the vicinity of predicted output. Furthermore, many rules extracted by our method were more confident and clearer supported by evidences from biological literature than any rules reported so far. Our method resulted in an improvement of

2.5 percent as compared to the best results on the RS126 data set of 126 nonhomologous globular proteins [4], achieved previously by a rule extraction method.

The paper is organized as follows: Section 2, Methods, describes TS-SVM and C4.5 decision tree technique. Section 3, Experiments and Results, describes the data sets used, simulations made, and discusses extracted rules. Section 4, Discussion, provides concluding remarks for the analyses made.

2   METHODS

2.1   Two-Stage SVM

Let $\mathbf{u} = (u_1, u_2, \ldots, u_n)$ be a given amino acid sequence, where $u_i \in \Omega_U$ and Ω_U denotes the set of 20 amino acid residues, and $\mathbf{t} = (t_1, t_2, \ldots, t_n)$ be the corresponding secondary structure sequence, where $t_i \in \Omega_T$ and the set of secondary structures, $\Omega_T = \{\alpha, \beta, \zeta\}$; n is the length of the sequence. The prediction of PSS sequence is the problem of finding the optimal mapping from the space of Ω_U to the space of Ω_T. Let $\mathbf{v}_i$ be the 21-dimensional feature vector representing residue u_i, where 20 values are from raw matrices of PSI-BLAST profiles ranging in $[0, 1]$ and the remaining unit is used for padding to indicate an overlapping end of the sequence [10]. Let $\mathbf{r}_i = (\mathbf{v}_{i-h_1}, \ldots, \mathbf{v}_i, \ldots, \mathbf{v}_{i+h_1})$ be the input to the multi-class SVM at site i of the sequence, where h_1 denotes the width of a symmetric neighborhood window of residues on one side. TS-SVM uses two multiclass SVMs in cascade for the prediction of protein features from amino acid sequences [14], [15], [16]. We use a multiclass SVM proposed by Crammer and Singer for both stages [18].

The first stage constructs three discriminant functions for three secondary structures by solving the single optimization problem:

$$\arg \min_{\mathbf{w}_1} \frac{1}{2} \sum_{k \in \Omega_T} \left(\mathbf{w}_1^k\right)^T \mathbf{w}_1^k + \gamma_1 \sum_{j=1}^N \xi_j^1$$

subject to the constraints

$$\mathbf{w}_1^{t_j} \phi_1(\mathbf{r}_j) - \mathbf{w}_1^k \phi_1(\mathbf{r}_j) \geq c_j^k - \xi_j^1, \qquad (1)$$

where t_j is the secondary structural type at site j corresponding to input vector $\mathbf{r}_j$. N is the size of the training data, and $\mathbf{w}_1^{t_j}$ and $\mathbf{w}_1^k$ are weight vectors corresponding to secondary structures t_j and k, and

$$c_j^k = \begin{cases} 0, & \text{if } t_j = k, \\ 1, & \text{if } t_j \neq k. \end{cases}$$

The above optimization is simplified by solving the following quadratic programming problem [18]:

$$\begin{aligned} \max_{\alpha_j^k} -\frac{1}{2} \sum_{j=1}^N \sum_{i=1}^N \mathcal{K}_1(\mathbf{r}_j, \mathbf{r}_i) \sum_{k \in \Omega_T} \alpha_j^k \alpha_i^k - \sum_{j=1}^N \sum_{k \in \Omega_T} \alpha_j^k c_j^k, \\ \text{such that } \sum_{k \in \Omega_T} \alpha_j^k = 0 \quad \text{and} \quad \alpha_j^k \leq \begin{cases} 0, & \text{if } t_j \neq k, \\ \gamma_1 & \text{if } t_j = k, \end{cases} \end{aligned} \qquad (2)$$

where $\mathbf{w}_1^k = \sum_{j=1}^N \alpha_j^k \phi_1(\mathbf{r}_j)$ and $\mathcal{K}_1(\mathbf{r}_i, \mathbf{r}_j) = \phi_1(\mathbf{r}_i)\phi_1(\mathbf{r}_j)$ denotes the kernel function. The input vectors, derived from a window of $2h_1 + 1$ amino acid residues, are transformed into a higher dimensional space via kernel function $\mathcal{K}_1$. Once the optimal parameters α_j^k are obtained, the discriminant function of structure k, f_1^k for an input $\mathbf{r}_i$ is given by

$$f_1^k(\mathbf{r}_i) = \sum_{j=1}^N \alpha_j^k \mathcal{K}_1(\mathbf{r}_i, \mathbf{r}_j) = \mathbf{w}_1^k \phi_1(\mathbf{r}_i). \qquad (3)$$

The second stage uses another SVM to predict PSS from the output of the first-stage SVM to enhance prediction accuracy by capturing the contextual dependences of secondary structures, for example,

β-strands span over at least three residues and α-helices composed of at least four residues [4], [14].

The input to the second SVM at site i is obtained from a neighborhood, $\mathbf{d}_i^1 = (d_{i-h_2}^{1k} \ldots, d_i^{1k} \ldots, d_{i+h_2}^{1k} : k \in \Omega_T)$ where $d_i^{1k} = 1/(1 + e^{-f_1^k(\mathbf{r}_i)})$ and h_2 is the size of the neighborhood on one side. The logistic sigmoid function is selected to normalize the inputs to the second stage to $[0, 1]$. The input patterns to the second stage are converted to a higher dimensional space by using a mapping ϕ_2 and a kernel function: $\mathcal{K}_2(\mathbf{d}_i^1, \mathbf{d}_j^1) = \phi_2(\mathbf{d}_i^1)\phi_2(\mathbf{d}_j^1)$. The outputs in the higher dimensional space are linearly combined by a weight vector $\mathbf{w}_2^k$ to produce the final prediction. The vector $\mathbf{w}_2^k$ is obtained by solving the following convex quadratic programming problem over all secondary structure sequences predicted by the first stage in the training stage. The secondary structural type $\hat{t}_i$ at site i of input sequence is estimated by

$$\hat{t}_i = \arg \max_{k \in \Omega_T} f_2^k(\mathbf{d}_i^1), \qquad (4)$$

where $f_2^k(\mathbf{d}_i^1) = \mathbf{w}_2^k \phi_2(\mathbf{d}_i^1)$ is the discriminant function at the second stage given as in (3).

2.2   Decision Trees

SVMs perform well compared to other statistical or machine learning techniques in predicting protein features [14], [15], [16], [17] because of their generalization capabilities. However, SVMs alone yield black box models and provide no biologically meaningful prediction rules [17]. Decision trees, on the other hand, are capable of explicitly describing the nature of prediction since they capture rules as prevailing regularities governing the prediction process. Prediction rules offer useful guidance for wet-lab experiments and a basis for advanced inference of biological features correlated to specific structures.

Decision tree learning provides a means of approximating discrete-valued target functions, in which the learned function is represented by a decision tree [19]. In order to improve human comprehensibility, learned decision trees can be re-represented as sets of if-then rules. We use C4.5 tree induction algorithm at the output of TS-SVM to generate rules for PSS prediction. C4.5 was chosen because it has been shown to extract more accurate rules in many applications including bioinformatics problems, for example, generating automatic rules for protein annotation, mining protein sequences in SWISS-PROT, and PSS prediction [17]. It uses the gain ratio criterion based on the information theory to select the attribute at the root of the tree and produces suboptimal trees by learning heuristically from input [20]. The important rules are generated by first creating a decision tree on a training set, and then pruning the tree by replacing a whole of subtree with a leaf node if a decision rule establishes a greater expected error rate in the subtree than that in the single leaf. Rule sets are then derived from writing a rule for each path in the decision tree from the root to a leaf. The leaf-hand side is easily built from the label of the nodes and the labels of the arcs.

Let the training set of exemplars for C4.5 decision tree be $\Gamma_{\text{train}}^2 = \{(\mathbf{a}_j, t_j) : j = 1, \ldots, N\}$, where the input at site j is $\mathbf{a}_j = (d_{j-h_2}^{2k} \ldots d_j^{2k}, \ldots d_{j+h_2}^{2k}, \mathbf{v}_{j-h_1}, \ldots \mathbf{v}_j, \ldots \mathbf{v}_{j+h_1})$ and t_j is the desired secondary structure, where $d_j^{2k} = 1/(1 + e^{-f_2^k(\mathbf{d}_j^1)})$. The training set is used to train the decision tree and to extract the corresponding rule sets. The rules are then tested with the same data set for evaluation of the performance of the algorithm.

3   EXPERIMENTS AND RESULTS

The presented approach was implemented using position-specific scoring matrices generated by PSI-BLAST as inputs and tested on benchmark with RS126 data set. The results were compared with other prediction methods and with other rule extraction results for

PSS on this data set. Separate rule extraction using the TS-SVM methods and C4.5 was also performed on PSIPRED data set of 1,923 proteins. Subsequently, a set of common rules for both data sets was identified as discussed below.

3.1 Data Sets

The set of 126 nonhomologous globular protein chains, used by Rost and Sander and referred to as the RS126 set [4], was used to evaluate the accuracy of the predictors and relevance of extracted rules. Many current PSS prediction methods have been developed and tested on this data set. To refer to most relevant reports in the literature, experiments on this data set were performed with sevenfold validation. The data set contained 23,349 residues with 32 percent α-helix, 23 percent β-strand, and 45 percent coil. The RS126 set is available at http://www.compbio.dundee.ac.uk/~www-jpred/data/pred_res/126_set.html.

A much larger data set PSIPRED [7] has also been used in this project to evaluate the TS-SVM predictors with and without C4.5. After eliminating 322 sequences with some unknown amino acids, experiments were performed on remaining 1,923 sequences using 10-fold validation. The data set is available at http://bioinf.cs.ucl.ac.uk/downloads/psipred/old/data.

The type of the secondary structure of each residue in training and testing sets was assigned from DSSP [4]. This reduction approach was adopted since it is commonly used for comparison of PSS prediction accuracies by other researchers [4], [5], [6], [7], [8], [9].

3.2 Implementation

The mostly used SVM software includes LibSVM (http://www.csie.ntu.edu.tw/~cjlin/libsvm/), Pls-SVM (http://www.esat.kuleuven.ac.be/sista/lssvmlab/), and SVM-Light (http://svmlight.joachims.org/). In this paper, the multiclass SVM method was implemented using BSVM library which is known to show fast convergence for large optimization problems [21]. The Gaussian kernel $\mathcal{K}(\mathbf{x}, \mathbf{y}) = e^{-\sigma \|\mathbf{x} - \mathbf{y}\|^2}$ showed superior performance over linear and polynomial kernels for predicting PSS [14], relative solvent accessibility [15], accessible surface areas of amino acids [16], and gene classification [22]. The sensitivity parameter γ and

the Gaussian kernel parameter σ were determined by using the grid search method [21]. Grid search provides good parameter estimates for multiclass SVM in a relatively short time. The parameters of the Gaussian kernel and TS-SVM, as $\sigma_1 = 0.0625$, $\sigma_2 = 0.0156$, and $\gamma_1 = \gamma_2 = 0.5$, and the neighborhood window $h_1 = 7$ and $h_2 = 3$ were empirically determined for optimal performance. We implemented the decision tree C4.5 by using Weka software [23]. For C4.5, the confidence factor of 60 percent was chosen, and an appropriate value for the minimum number of instances per leaf within [1, 60] was selected based on cross-validation results.

3.3 Prediction Accuracies

We used Q_3 accuracy to measure the percentages of correctly predicted residues of three types of secondary structures [8]:

$$Q_3 = \frac{\sum_{t \in \Omega_T} \eta_t}{\sum_{t \in \Omega_T} \upsilon_t} \times 100, \qquad (5)$$

where η_t is the number of correctly predicted residues and υ_t is the total number of residues observed of secondary structure type t. We also used a rule's *confidence* to indicate its accuracy verified on the whole data set. The confidences C_α, C_β, and C_ζ represent the percentages of correctly predicted residues of each type of secondary structure.

The performance of secondary structure prediction on the RS126 data set of 126 proteins by using TS-SVM and C4.5 is shown in Table 1. It can be seen that the combination of TS-SVM and C4.5 predicted PSS with the highest average accuracy (75.0 percent) in comparison to C4.5 alone (58.6 percent), and to the combination of SVM with C4.5 (73.7 percent). It should be noted that the combination of TS-SVM and C4.5 decision trees generates fewer rules than SVM + C4.5 or C4.5 alone, while also yielding higher accuracy of prediction even with fewer rules. In addition, a decision tree with smaller number of leaves makes rules more comprehensible, and at the same time, more reliable. Less leaves means that, on average, there are more examples per leaf that give the rule better statistical conformation.

Table 2 shows comparative performance of different PSS on the RS126 set without C4.5 rules (rows 2 and 4) and with C4.5 rules (rows 1, 3, and 5). The results indicate that after combining SVM or TS-SVM with C4.5 decision trees, the accuracy of the combinations

drops by 3 percent and 1.6 percent, respectively, because of pruning of less significant rules. This occurs when some amino acid patterns contributing to the prediction, but occurring rarely in the data set, are filtered out during pruning when building decision trees. Table 2 also shows an improvement of 2.5 percent in prediction accuracy (see rows 1 and 3) of our approach compared to the method of He et al. produced on RS126 by combining single-stage binary SVM with C4.5 [17]. Though the method only reported the accuracies of three binary SVM classifiers, we computed the overall prediction accuracy from the counts of structure types as 72.5 percent.

To validate the rules extracted by our approach on different training and testing data sets, we have used the rules produced with a confidence level above 60 percent on PSPIRED and computed the accuracy on an RS126 data set. The accuracy of 76.1 percent shows that our approach has the ability to perform well on different training and testing data sets.

3.4 Extracted Rules

Subsequent description concerns rules extracted using the C4.5 method from TS-SVM predicting model. Overall number of rules produced with confidence level above 60 percent was 56 and 523, on RS126 and PSPIRED data sets, respectively. This count includes all rules of three different types as defined below. In the discussion to follow, we have, however, reduced the set of all rules to the subset being intersection of both sets. It jointly identifies 32 common rules that cover both sets for which we are seeking biological relevance and potential interpretability across both data sets.

Below, we partitioned the common rules into three categories I, II, and III, based on whether TS-SVM already predicted the specific secondary structure. The rules are shown in Tables 3, 4, and 5. The bold amino acid indicates the position of the secondary structure. The symbol "x" indicates a "do not care" condition for the amino acid in that site.

The confidence of the rules on each data set is given in the third and fourth column of the tables, respectively. The co-occurrences of such patterns with a specific secondary structure were the basis of prediction of PSS in GOR methods [1]. As can be seen from all the tables, the presented method resulted in more accurate predictions than those based on linear associations in the GOR method. This is because of the complex nonlinear mapping by TS-SVM and extraction of relevant rules transforming patterns of amino acids to secondary structures. To show the usefulness and

biological relevance of the rules, we interpret some of the derived rules by discussing evidence found in the literature.

3.4.1 Type I Rules

Type I rules extracted by the presented method are shown in Table 3. Listed are rules common for two data sets with variable confidence above 60 percent, indicating which amino acid patterns lead to the prediction of specific protein secondary structures. The first two rules indicate that the method predicts an α-helix when patterns **L**xx**M** and **V**x**AL** are present, with 66.7 percent and 60.0 percent confidence, and 60 percent and 64 percent confidence, respectively. As seen, Leucine (L, Leu) and Methionine (M, Met) are present at three sites downstream of the site. Amino acids L and M are nonpolar R group (hydrophobic) and tend to form α-helix, and their presence at three sites downstream proves to be helix-stabilizing.

It has been previously reported that L-L, L-V, L-I, F-M, and L-M pair at the local site and occur commonly three and four sites downstream in a-helices and contribute to protein's structural stability [24]. Experimental and theoretical studies on natural and synthetic peptides and proteins indicate that individual side chains differ in their potential of helix-forming. Four aliphatic side chains occur in the standard complement of amino acids: L and A are helix-stabilizing whereas V and I are weakly destabilizing helices [25]. From position-specific amino acid preferences in a-helices [26], there is a peak preference for hydrophobic amino acids L and V in positions N4 (N-cap + 4) and C3 (C-cap − 3) and M in position C4 (C-cap − 4). Helix boundary residues (the first and last helical residues) are called N-cap and C-cap at the N- and C-terminus, respectively. Positions N4 and C4 are underneath the polypeptide chain leading the helix, and also usually on its interior face as the chain at each end must connect to the rest of the protein [26].

As also seen from Table 3, patterns **D**Vx**LG**, **S**Vx**VG**, **W**Vx**IG**, and TV**TV**, predict β-strands with 100 percent confidence for RS126 and somewhat lower confidence levels for PSPIRED, as shown in the rightmost column. Rule 3 shows that if Aspartic acid (D, Asp) is present at a site and Valine (V, Val), Leucine (L, Leu), and Glycine (G, Gly) at one, three, and four sites downstream, respectively, then the secondary structure at the site will be a β-strand. This rule suggests that negatively charged (hydrophilic) amino acid D at the local site and nonpolar R group (hydrophobic) amino acids V, L, and G downstream, prove to be sheet-stabilizing. Colloc'h and Cohen focused their attention on the conformational and structural properties of residues that initiate or terminate a β-strand [27] and are referred to as β-breakers because of their role in breaking the regular geometric structure of the strand. They found a preference for D, T, and R as the N-terminal β-breaker and G and S as the C-terminal β-breaker. Interestingly, our previous work found that hydrophobic amino acids V and I strongly tend to be β-strand [14]. Moreover, in rules 6 and 7 in Table 3, the weakly hydrophilic amino acid T is two sites upstream, the non-polar R group (hydrophobic) amino acid V is one site upstream, then another nonpolar R group (hydrophobic) amino acids I or weakly hydrophilic amino acid T is the local site, and finally, another hydrophobic amino acid V. If this forms a sheet, then the two hydrophobic amino acids C and V move in the same direction (possibly into the core of the protein), and the hydrophilic amino acid T could then face the solvent [17].

Further, in rule 8 in Table 3, pattern A**V**P predicts a coil with 100 percent and 72.7 percent confidence, respectively. Amino acid Proline (P, Pro) invariably shows a high frequency of occurrence at neighboring positions of all coil sites. Given the unique structural feature of amino acid P where its side-chain is bonded to the main-chain N atom, the conformation of the polypeptide backbone is often perturbed by the presence of amino acid P, and therefore, is induced to form coils in proteins [28]. Rule 10 in Table 3 shows that if Aspartic acid (D, Asp) is present at a site with Tyrosine (Y, Tyr)

two sites downstream, then a coil is predicted with 65.2 percent and 60 percent confidence, respectively. The amino acid D in negatively charged R group (hydrophilic) and Y in aromatic R group (hydrophobic) tend to create coil, spanning over at least three adjacent residues [14], and making the likelihood of a presence of the secondary structure stronger. Crasto and Feng found that amino acid D has a moderate preference for coil conformation and the coil propensities of amino acids Y and P have significant variations in coils of different sizes [28]. Also, charged amino acids D and K have lower frequencies of occurrence in the interior than in the surface coils.

3.4.2 Type II Rules

Table 4 lists type II rules or the amino acid patterns that enhance the prediction of a secondary structure by C4.5 if the presence of the secondary structure is already known for TS-SVM prediction. The prediction accuracy of α-helices by TS-SVM alone stands at 73.1 percent (see Table 2). The decision tree predicts an α-helix for patterns GxxY, MxxS, **D**xxxxxx**Y**, and PxN**x** if TS-SVM predicts the site to be an α-helix (rules 11-14). The confidence level of the decision tree prediction is 100 percent for RS126 and exceeds 88 percent for PSIPRED. The above rules can be given a different interpretation: when one of the four above amino acid patterns appear, then the surrounding patterns of amino acid make the confidence of prediction to be at least 88 percent.

For illustration, consider rule 16 in Table 4, which indicates that if hydrophilic amino acid Serine (S, Ser) is at one site upstream, Proline (P, Pro) is present at the local site, Aspartic acid (D, Asp) is at two sites downstream, and TS-SVM predicts the local site to be an α-helix, then the pattern S**P**x**D** is present with 89.3 percent and 83.3 percent confidence, respectively. For this pattern, hydrophilic amino acid S followed the hydrophobic amino acid P and another hydrophilic amino acid D at two sites downstream proves to be helix-stabilizing if the amino acid P forms an α-helix. From position-specific amino acid preferences in a-helices [26], the N-cap position is dominated by amino acid S. This is because when amino acid S does occur in α-helix, its OH often forms a second H bond to a backbone CO on the previous helical turn. The preference distribution for amino acid P indicated that amino acid P in the first turn is almost exclusively in the N1 position (the first residue after the N-cap) [26]. This rule concurs with the findings of Richardson et al. that amino acid P prefers to be a helix initiator than a helix breaker [26]. Also, there is a peak of preference for hydrophilic amino acid D in positions N2 and N3 (the second and third residue after the N-cap).

Moreover, results in Table 4 indicate that the presence of the amino acids with the known secondary structure type at the local site improves the confidence of the secondary structure prediction.

3.4.3 Type III Rules

The patterns expressed by rules of type III listed in Table 5 make use of the secondary structures predicted by TS-SVM not only at the site but also at adjacent sites. Interestingly, the presence of a secondary structure at a particular location is associated here with the presence of the same structure in the vicinity.

For instance, rule 29 shows that if Cystine (C, Cys) is at four sites upstream, Arginine (Arg, R) is at four sites downstream, and an α-helix is predicted by TS-SVM at two sites upstream, at two sites downstream, and at the local site, then the secondary structure is predicted as an α-helix with 100 percent and 93.3 percent confidence. This result suggests that hydrophilic amino acids C at four sites upstream and R at four sites downstream prove to be helix-stabilizing if the amino acids at two sites upstream, two sites downstream, and the local site form an α-helix.

As shown in Table 5, the pattern of rule 29 given the secondary structural type of α-helix at the local site indicates they stabilize

helix. Also, in rule 29 in Table 5, amino acid R in positively R-charged group (hydrophilic) strongly tends to be α-helix and helices consist of at least four consecutive residues [14], and therefore, the secondary structure of the target is a strong α-helix.

Rule 32 in Table 5 demonstrates that if hydrophobic amino acid Glycine (G, Gly) is two sites upstream, Leucine (L, Leu) is present at the local site, and TS-SVM predicts the local site and one site downstream to be coils, the pattern GxLx/ζ is present with 71.1 percent and 78.1 percent confidence, respectively. For this pattern, hydrophobic amino acid L is known to have low coil propensities; however, these amino acids have high propensities at neighboring positions of G in coils [28]. Amino acid G is commonly found at neighboring positions of hydrophobic Isoleucine (I, ILE), Leucine (L, Leu), and hydrophilic coil residues.

4   DISCUSSION

Utilizing the PSS predictions made by TS-SVM approach, we employed C4.5 decision trees to generate prediction rules. As manifested by the experiments, we were able to extract three types of joint prediction rules on RS126 and PSIPRED data sets. To generate a set of prevailing rules that can also be interpreted, we used empirically preset confidence threshold of 60 percent. The number of rules derived was relatively small and they showed higher confidence levels compared to those derived by other approaches. The rules were divided into three types based on whether the secondary structures predicted by TS-SVM were already included in the prediction rule. The number of structures in each rule in the data sets range from 11 to 813. The final overall prediction accuracies of TS-SVM+C4.5 were lower than that of TS-SVM alone because of pruning of less confident rules in the decision tree. However, our overall accuracies were better than earlier methods combining binary/multiclass SVM with C4.5 [17]. The reason is that the contextual effects on structural formations on a secondary structure at a particular site by the neighbouring structures are taken into account for prediction by TS-SVM. As can be seen from Table 2, lower overall accuracies after incorporating C4.5 are mainly due to the low prediction accuracies of coil structures. Interestingly, by narrowing down the patterns responsible for PSS prediction, improvements of accuracies of α-helices and β-strands were seen which carry important structural formation. Coils account for remaining structural patterns of proteins.

Recently, the rules based on decision tree algorithms have been effectively extracted from a thermodynamic database of proteins and mutants to explore potential knowledge of protein stability prediction [29]. The performance of decision trees is better than the other methods for predicting changes of protein stability on a thermodynamic data set consisting of 1,615 mutants [30]. The results of the experiments for protein structure prediction show that the rules extracted by decision trees have meaningful biological interpretation and their comprehensibility is better than that of other methods [31].

Most rules extracted by the presented approach have significant and meaningful biological interpretation. As seen, the presence of specific amino acids improves the confidence of the secondary structure prediction. This could be interpreted as the confidences of the existence of a secondary structure pattern due to the presence of a particular amino acid pattern in the neighborhood. After assignment of secondary structures, structural classes can be assigned to domains that provide an excellent source for further analysis. Structural classes divide proteins according to secondary structure content and organization. Amino acids and structural patterns based on type III rules can be extended for domains with predominantly α-helices or β-sheets.

The inspection of the prediction rules has offered interesting new insights into stabilizing α-helix, β-strand, and coil structures. Our results concur with the findings of Lyu et al. that amino acid L (Leu) tends to be helix-stabilizing [34]. The preferences for amino acids T (Thr), R (Arg), and G (Gly) in β-strand prediction rules indicate their role in breaking the regular structure of the strands [28]. The rules of prediction of coils confirm that the most influential amino acids (the affecters) in coils are P (Pro) and G (Gly) [28]. The analysis of the prediction rules also shows that the neighboring residues could have a profound effect on the preference of certain amino acids adopting α-helix, β-strand, and coil structures. Recently, the rule extraction method of He et al. uses one stage of binary SVM, which is unable to capture contextual relationships among the secondary structures. Therefore, the rules for β-strand prediction were less than 90 percent confidence on RS126 data set [17].

Furthermore, these rules could be useful for guiding biological experiments aimed at satisfying the sequence conditions to produce a certain protein structure. There are several proteins that bind to membranes via a small amphipathic helix with one face made of hydrophobic residues [32]. In the study of Mad1 and mSin3A interaction, Eilers et al. determined that the hydrophobic face of amphipathic alpha-helical structure makes key contacts with mSin3A [33]. With our protein secondary structure prediction, the amphiphilicity of the predicted helix can be inferred by calculating the helix hydrophobic moment [34].
