Provably Secure Group Signature Schemes from Code-Based Assumptions

Martianus Frederic Ezerman, Hyung Tae Lee, San Ling, Khoa Nguyen, and Huaxiong Wang

Abstract—We solve an open question in code-based cryptography by introducing two provably secure group signature schemes from code-based assumptions. Our basic scheme satisfies the CPA-anonymity and traceability requirements in the random oracle model, assuming the hardness of the McEliece problem, the Learning Parity with Noise problem, and a variant of the Syndrome Decoding problem. The construction produces smaller key and signature sizes than the previous group signature schemes from lattices, as long as the cardinality of the underlying group does not exceed $2^{24}$, which is roughly comparable to the current population of the Netherlands. We develop the basic scheme further to achieve the strongest anonymity notion, i.e., CCA-anonymity, with a small overhead in terms of efficiency. The feasibility of two proposed schemes is supported by implementation results. Our two schemes are the first in their respective classes of provably secure groups signature schemes. Additionally, the techniques introduced in this work might be of independent interest. These are a new verifiable encryption protocol for the randomized McEliece encryption and a novel approach to design formal security reductions from the Syndrome Decoding problem.

Index Terms—code-based group signature, zero-knowledge protocol, McEliece encryption, syndrome decoding.

I. INTRODUCTION

A. Background and Motivation

Group signature [11] is a fundamental cryptographic primitive with two intriguing features. The first one is anonymity. It allows users of a group to anonymously sign documents on behalf of the whole group. The second one is traceability. There exists a tracing authority that can tie a given signature to the signer’s identity should the need arise. These two properties make group signatures highly useful in various real-life scenarios such as controlled anonymous printing services, digital right management systems, e-bidding and e-voting schemes. Theoretically, designing secure and efficient group signature schemes is of deep interest since doing so typically requires a sophisticated combination of carefully chosen cryptographic ingredients. Numerous constructions of group signatures have been proposed. Most of them, e.g., the respective schemes in [2], [3], [4], [5], and [6], are based on classical number-theoretic assumptions.

While number-theoretic-based group signatures, such as those in [3] and [4], can be very efficient, they would become insecure once the era of scalable quantum computing arrives [7]. Prior to our work, the search for group signatures that have the potential to be secure against quantum computers, as a preparation for the future, has been quite active, with at least six published schemes [8], [9], [10], [11], [12], [13]. All of them are based on computational assumptions from lattices. Despite their theoretical interest, the schemes require significantly large key and signature sizes. None of them has been supported by implementation results. Our evaluation, in Section II-B below, shows that these lattice-based schemes are indeed very far from being practical. This somewhat unsatisfactory situation highlights two interesting challenges. The first one is to push group signatures from quantum-resistant assumptions closer to practice. The second one is to bring more diversity in, with schemes from other candidates for post-quantum cryptography, e.g., code-based, hash-based, and multivariate-based. An easy-to-implement and competitively efficient code-based group signature scheme, for instance, would be highly desirable.

A code-based group signature, in the strongest security model for static groups as discussed in [14], typically requires the following three cryptographic layers.

1) The first layer requires a secure (standard) signature scheme to sign messages. Note that in most schemes based on the model in [14], a standard signature is also employed to issue the users’ secret keys. However, this is not necessary. The scheme constructed in this paper is an illustrative example. We observe that existing code-based signatures fall into two categories. The “hash-and-sign” category consists of the CFS signature [15] and its modified versions [16], [17], [18]. The known security proofs for schemes in this category, however, should be viewed with skepticism. The assumption used in [16], for example, had been invalidated by the distinguishing attacks detailed in [19], while the new assumption proposed in [18] lies on a rather fragile ground.
The “Fiat-Shamir” category consists of schemes derived from Stern’s identification protocol in [20] and its variants in [21], [22], and [23] via the Fiat-Shamir transformation from [24]. Although these schemes produce relatively large signatures, as the underlying protocol has to be repeated many times to make the soundness error negligibly small, their provable security, in the random oracle model, is well-understood.

2) The second layer demands a **semantically secure encryption scheme** to enable the tracing feature. The signer is constrained to encrypt its identifying information and to send the ciphertext as part of the group signature, so that the tracing authority can decrypt if and when necessary. This ingredient is also available in code-based cryptography, thanks to various CPA-secure and CCA-secure variants of the McEliece [25] and the Niederreiter [26] cryptosystems available in, e.g., [27], [28], [29], and [30].

3) The third layer requires a **zero-knowledge (ZK) protocol** that connects the previous two layers. This is essentially the bottleneck in realizing secure code-based group signatures. Specifically, the protocol should demonstrate that a given signature is generated by a certain certified group user who honestly encrypts its identifying information. Constructing such a protocol is quite challenging. There have been ZK protocols involving the CFS and Stern’s signatures, which yield identity-based identification schemes in [31], [32], and [33] and threshold ring signatures in [34] and [35]. There have also been ZK proofs of plaintext knowledge for the McEliece and the Niederreiter cryptosystems [36]. Yet we are unaware of any efficient ZK protocol that simultaneously deals with both code-based signature and encryption schemes in the above sense.

Designing provably secure group signature schemes has been a long-standing open question in code-based cryptography, as was also discussed in [37].

### B. Our Contributions

This work introduces two group signature schemes which are provably secure under code-based assumptions. Specifically, our basic scheme achieves the CPA-anonymity [4] and the traceability requirements in [14] in the random oracle model. We assume the hardness of the McEliece problem, the Learning Parity with Noise problem, and a variant of the Syndrome Decoding problem. The basic scheme is then extended to achieve anonymity in the strongest sense [14], i.e., CCA-anonymity, for which the adversary is allowed to adaptively query for the opening of group signatures. Our two schemes are the first of their respective classes.

#### Contributions to Code-Based Cryptography

By introducing provably secure code-based group signature schemes, we solve the open problem discussed earlier. Along the way, we introduce the following two new techniques for code-based cryptography, which might be of independent interest.

1) We design a ZK protocol for the randomized McEliece encryption scheme. The protocol allows the prover to convince the verifier that a given ciphertext is well-formed and that the hidden plaintext satisfies an additional condition. Such **verifiable encryption protocols** are useful, not only in constructing group signatures, but also in much broader contexts [38]. It is worth noting that, prior to our work, verifiable encryption protocols for code-based cryptosystems only exist in a very basic form where the plaintext is publicly given [36], restricting their applications.

2) In our security proof of the traceability property, to obtain a reduction from the hardness of the Syndrome Decoding (SD) problem, we come up with an approach that, to the best of our knowledge, has not been considered in the literature before. Let us recall the (average-case) SD problem with parameters $m, r, \omega$. Given a uniformly random matrix $H \in F_2^{m \times m}$ and a uniformly random syndrome $\tilde{y} \in F_2^m$, the problem asks to find a vector $s \in F_2^m$ of Hamming weight $\omega$, denoted by $s \in B(m, \omega)$, such that $H \cdot s^\top = \tilde{y}^\top$. In our scheme, the key generation algorithm produces a public key that contains a matrix $H \in F_2^{m \times r}$ and syndromes $\tilde{y}_j \in F_2^m$, while users are given secret keys of the form $s_j \in B(m, \omega)$ such that $H \cdot s_j^\top = \tilde{y}_j^\top$. In the security proof, since we would like to embed an SD challenge instance $(H, \tilde{y})$ into the public key without being noticed, except with negligible probability, by the adversary, we have to require that $H$ and the $y_j$’s produced by the key generation are indistinguishable from uniform.

One method to generate these keys is to employ the “hash-and-sign” technique from the CFS signature [15]. Unfortunately, while the syndromes $y_j$’s could be made uniformly random, as the outputs of the random oracle, the assumption that the CFS matrix $H$ is computationally close to uniform for practical parameters is invalidated by the distinguishing attacks from [19].

Another method, pioneered by Stern [20], is to pick $H$ and the $s_j$’s uniformly at random. The corresponding syndromes $y_j$’s could be made computationally close to uniform provided that the parameters are set to make $\omega$ slightly smaller than the value $\omega_0$ given by the Gilbert-Varshamov bound, i.e., $\omega_0$ is such that $\binom{m}{\omega_0} \approx 2^r$. In such a case, the function $f_H(s_j) = H \cdot s_j^\top$ acts as a pseudorandom generator [39]. However, for these parameters, it is not guaranteed with high probability that a uniformly random SD instance $(H, \tilde{y})$ has solutions, which would affect the success probability of the reduction algorithm. Our work considers the case when $\omega$ is moderately larger than $\omega_0$, so that two conditions hold. First, the uniform distribution over the set $B(m, \omega)$ has sufficient min-entropy to apply the Left-over Hash Lemma from [40]. Second, the SD problem with parameters $(m, r, \omega)$ admits solutions with high probability, yet remains intractable against the best known attacks from [42] and [43]. Note that the variant of the SD problem considered in this work are not widely believed to be the hardest one [20], [41], but suitable parameters can be chosen such that the best known attacks run in exponential time.
Although we are yet to obtain security proofs in the quantum random oracle model (QROM), our constructions provide the first non-lattice-based alternatives to provably secure group signatures from quantum-resistant assumptions. Our schemes feature public key and signature sizes that are comparable to the current population of the Netherlands. Our schemes are set as in Section VI. For the scheme in [13], the public key and signature sizes are 29 bits and 210 = 65,536, respectively, compared to the basic scheme. Table I gives the details of our estimation. The parameters for our schemes are set as in Section VI. For the scheme in [13], we choose the commonly used lattice dimension \( n = 2^8 \) and set the parameters \( m = 2^9 \times 150 \) and \( q = 2^{150} \) to satisfy the requirements given in [13] Section 5.1. While our basic scheme and the scheme in [13] achieve the CPA-anonymity notion [4], our extended scheme achieves the CCA-anonymity notion [4]. All schemes have soundness error \( 2^{-80} \).

We give actual implementation results for our proposed schemes to support their claim of feasibility. In our implementations, as presented later in Section VI the actual signature sizes can be reduced thanks to an additional technique. Our schemes are the first group signature from quantum-resistant assumptions that comes supported with an actual deployment analysis. The results, while not yielding a truly practical scheme, certainly help in bringing this new class of group signatures closer to practice.

### C. Overview of Our Techniques

Let \( m, r, \omega, n, k, t \) and \( \ell \) be positive integers. We consider a group of size \( N = 2^\ell \), where each user is indexed by an integer \( j \in \{0, N - 1\} \). The secret signing key of user \( j \) is a vector \( s_j \) chosen uniformly at random from the set \( B(m, \omega) \). A uniformly random matrix \( \mathbf{H} \in \mathbb{F}_2^{r \times m} \) and \( N \) syndromes \( y_0, \ldots, y_{N-1} \in \mathbb{F}_2^r \), such that \( \mathbf{H} \cdot s_j = y_j^\top \), for all \( j \), are made public. Let us now explain the development of the three ingredients used in our basic scheme.

#### The Signature Layer. User \( j \) can run Stern’s ZK protocol [20] to prove the possession of a vector \( s \in B(m, \omega) \) such that \( \mathbf{H} \cdot s^\top = y_j^\top \). The constraint \( s \in B(m, \omega) \) is proved in ZK by randomly permuting the entries of \( s \) and showing that the permuted vector belongs to \( B(m, \omega) \). The protocol is then transformed into a Fiat-Shamir signature [24]. However, such a signature is publicly verifiable only if the index \( j \) is given to the verifier.

The user can further hide its index \( j \) to achieve unconditional anonymity among all \( N \) users. This, incidentally, yields a ring signature [45] on the way, à la [46]. Let \( \mathbf{A} = [y_0^\top \mid \cdots \mid y_j^\top \mid \cdots \mid y_{N-1}^\top] \in \mathbb{F}_2^{r \times N} \). Let \( x = \delta_N^j \) be the \( N \)-dimensional unit vector with entry 1 at the \( j \)-th position and 0 elsewhere. Observe that \( \mathbf{A} \cdot x^\top = y_j^\top \), and thus, the equation \( \mathbf{H} \cdot s^\top \oplus \mathbf{A} \cdot x^\top = 0 \),

\[
\mathbf{H} \cdot s^\top \oplus \mathbf{A} \cdot x^\top = 0, \quad (1)
\]

where \( \oplus \) denotes addition modulo 2. Stern’s framework allows the user to prove in ZK the possession of \( (s, x) \) satisfying this equation, where the condition \( x = \delta_N^j \) can be justified using a random permutation.

#### The Encryption Layer. To enable the tracing capability of the scheme, we let user \( j \) encrypt the binary representation of \( j \) via the randomized McEliece encryption scheme [27]. Specifically, we represent \( j \) as

\[
|2B(j) = (j_0, \ldots, j_{\ell - 1}) = \{0, 1\}^\ell, \quad \sum_{i=0}^{\ell-1} j_i 2^{\ell-1-i} = j.
\]

Given a public encrypting key $G \in F_{2}^{k \times n}$, a ciphertext of $I2B(j)$ is of the form
\[
c = (u \parallel I2B(j)) \cdot G + e \in F_{2}^{n},
\]
where $(u, e)$ is the encryption randomness, with $u \in F_{2}^{k-f}$ and $e \in B(n, t)$, i.e., $e$ is a vector of weight $t$ in $F_{2}^{n}$.

Connecting the Signature and Encryption Layers. User $j$ must demonstrate that it does not cheat, e.g., by a method originally proposed by Langlois
\[
\text{challenge is to establish a connection, which must be verifiable}
\]
and then made non-interactive, resulting in a non-interactive ZK argument of knowledge $\Pi$. The final group signature is of the form $(c, \Pi)$, where $c$ is the ciphertext. In the random oracle model, the anonymity of the scheme relies on the zero-knowledge property of $\Pi$ and the CPA-security of the randomized McEliece encryption scheme, while its traceability is based on the hardness of the variant of the SD problem discussed earlier.

**Achieving CCA-Anonymity.** Our basic group signature scheme makes use of the randomized McEliece encryption scheme that achieves only CPA-security. Hence, it only satisfies CPA-anonymity for which the adversary is not granted access to the signature opening oracle. To achieve the strongest notion of anonymity put forward in [13], i.e., CCA-anonymity, we would need a CCA2-secure encryption scheme so that we can respond to adaptive opening queries from the adversary by invoking the decryption oracle associated with the encryption mechanism. There are a number of known CCA2-secure code-based encryption schemes, e.g., [28], [29], [30]. They are, however, either too inefficient, say with ciphertext size quadratic in the security parameter, or incompatible with zero-knowledge protocols for proving the well-formedness of ciphertexts. Hence, they are unsuitable for our purpose. Instead, we exploit the fact that our verifiable encryption protocol for the randomized McEliece scheme is a simulation-sound ZK argument of knowledge. We then upgrade the encryption system further to a CCA2-secure one via the Naor-Yung twin encryption paradigm [51]. The protocol operates in Stern’s framework and satisfies the “quasi-unique responses” property in [48], deriving simulation-soundness from soundness. This fact was recently exploited by several group signature schemes, e.g., [49] and [50], which are based on Stern-like protocols.

Specifically, we will work with two public keys $G^{(1)}$ and $G^{(2)}$ of the randomized McEliece encryption scheme. The user now encrypts $I2B(j)$ under each of the keys to obtain ciphertexts $c^{(1)}$ and $c^{(2)}$, respectively, and extend the verifiable encryption protocol discussed above to prove that these ciphertexts are well-formed and correspond to the same plaintext $I2B(j)$, which is the binary representation of the user’s index $j$. This extension is quite smooth, since the same techniques for handling ciphertext $c$ can be used to handle $c^{(1)}$ and $c^{(2)}$. In the proof of CCA-anonymity, we then employ the strategy of [52] that makes use of the CPA-security of the underlying encryption scheme and the zero-knowledge, soundness and simulation-soundness of the resulting non-interactive argument. In terms of efficiency, our CCA-anonymous construction only has a small and reasonable overhead compared to its CPA-anonymous version, with one more McEliece encrypting matrix in the group public key and one more ciphertext equipped with its supporting ZK sub-protocol in the group signature.
D. Related Works

The present paper is the full extension of our earlier work [53], which was published in the proceedings of ASIACRYPT 2015. Achieving CCA-anonymity for code-based group signatures was raised as an open question in [53]. We are able to fully address the problem in this work.

In a work concurrent to and independent of [53], Alamélou et al. also proposed a code-based group signature scheme in [54] and, later on, in [55]. Their scheme considers the setting of dynamic groups. It does not use any encryption mechanism to enable traceability. Instead, the authors rely on a modified version of Stern’s protocol that allows the opening authority to test whether each protocol execution is generated using a secret key of a given user. Unfortunately, such approach does not yield a secure group signature. Recall that Stern’s protocol admits a soundness error of $2/3$ in each execution. It has to be repeated $n = \omega(\log \lambda)$ times, where $\lambda$ is the security parameter, to make the error negligibly small.

Nguyen et al. [57] recently proposed a number of new code-based privacy-preserving cryptographic constructions, including the first code-based group signature scheme with logarithmic signature size – which resolves an interesting question we left open in [53]. In their scheme, group users are associated with leaves in a code-based Merkle tree supported by a zero-knowledge argument of tree inclusion, which has communication cost linear in the tree depth (and hence, logarithmic in the number of users). Although their scheme achieves better asymptotic efficiency than ours, it yields signature size larger than 2.5 MB even for small groups. In particular, for groups of size up to $2^{16}$, the signatures are longer than those produced by our CPA-anonymous and CCA-anonymous schemes.

Subsequent to the publication of [53], a number of lattice-based group signatures have been proposed, bringing group signatures from quantum-resistant assumptions much closer to practice. Examples include the works done in [49], [50], [58], [59], and [60]. We believe that this interesting research direction will continue to attract attention from the community. The hope is that some provably secure and truly practical schemes can be realized in the near future.

II. Preliminaries

Notations. Let $\lambda$ be the security parameter and $\text{negl}(\lambda)$ denote a negligible function in $\lambda$. We use $a \leftarrow A$ if $a$ is chosen uniformly at random from the finite set $A$. The symmetric group of all permutations of $k$ elements is denoted by $S_k$. Bold capital letters, e.g., $A$, denote matrices. Bold lowercase letters, e.g., $x$, denote row vectors. We use $x^\top$ to denote the transpose of $x$ and $wt(x)$ to denote the (Hamming) weight of $x$. We denote by $B(m, \omega)$ the set of all vectors $x \in \mathbb{F}_2^n$ such that $wt(x) = \omega$. Throughout the paper, we define a function $\text{I2B}$ which takes a non-negative integer $a$ as an input, and outputs the binary representation $(a_0, \ldots, a_{t-1}) \in \{0, 1\}^t$ of $a$, and outputs $a$. All logarithms are in base 2.

A. Background on Code-Based Cryptography

We first recall the Syndrome Decoding problem. It is well-known to be $\text{NP}$-complete [61], and is widely believed to be intractable in the average case for appropriate choice of parameters [20], [41].

Definition 1 (The Syndrome Decoding problem): The SD$(m, r, \omega)$ problem asks, given a uniformly random matrix $H \in \mathbb{F}_2^{r \times m}$ and a uniformly random syndrome $s \in \mathbb{F}_2^r$, for a vector $y \in B(m, \omega)$ such that $H \cdot s^\top = y^\top$. When $m = m(\lambda)$, $r = r(\lambda)$ and $\omega = \omega(\lambda)$, the SD$(m, r, \omega)$ problem is hard if the success probability of any PPT algorithm in solving the problem is at most $\text{negl}(\lambda)$.

In our security reduction, the following variant of the Left-over Hash Lemma for matrix multiplication over $\mathbb{F}_2$ is used. 

Lemma 1 (Left-over Hash Lemma, adapted from [40]): Let $D$ be a distribution over $\mathbb{F}_2^m$ with min-entropy $\epsilon$. For $\epsilon > 0$ and $r \leq e - 2 \log(1/\epsilon) - O(1)$, the statistical distance between the distribution of $(H \cdot H \cdot s^\top)$, where $H \leftarrow \mathbb{F}_2^{r \times m}$ and $s \in \mathbb{F}_2^m$ is drawn from distribution $D$, and the uniform distribution over $\mathbb{F}_2^{r \times m} \times \mathbb{F}_2^m$ is at most $\epsilon$.

In particular, if $\omega < m$ is an integer such that
\[
r \leq \log \left(\frac{m}{\omega}\right) - 2\lambda - O(1)
\]
and $D$ is the uniform distribution over $B(m, \omega)$, i.e., $D$ has min-entropy $\log(\frac{m}{\omega})$, then the statistical distance between the distribution of $(H \cdot H \cdot s^\top)$ and the uniform distribution over $\mathbb{F}_2^{r \times m} \times \mathbb{F}_2^m$ is at most $2^{-\lambda}$.

The Randomized McEliece Encryption Scheme. We employ the following randomized variant, suggested in [27], of the McEliece encryption scheme [25], where a uniformly random vector is concatenated to the plaintext.

1) ME.Setup(1^\lambda): Select $n = n(\lambda)$, $k = k(\lambda)$, and $t = t(\lambda)$ as the parameters for a binary $[n, k, 2t+1]$ Goppa code. Choose integers $k_1$ and $k_2$ such that $k = k_1 + k_2$. Set the plaintext space as $\mathbb{F}_2^{k_1}$. 

2) ME.KeyGen\((n, k, t)\): Perform the following steps.
a) Produce a generator matrix \(G' \in F_2^{k \times n}\) of a randomly selected \([n, k, 2t + 1]\) Goppa code. Choose a random invertible matrix \(S \in F_2^{n \times n}\) and a random permutation matrix \(P \in F_2^{n \times n}\). Let \(G = SP\) \(\in F_2^{k \times n}\).
b) Output encrypting key \(pk_{ME} = G\) and decrypting key \(sk_{ME} = (S, G', P)\).

3) ME.Enc\((pk_{ME}, m)\): To encrypt a message \(m \in F_{2^k}\), get \(u \leftarrow F_2^k\) and \(e \leftarrow \mathcal{B}(n, t)\), then output the ciphertext 
\[
c = (u|m) \cdot G + e \in F_{2^n},
\]
where \(Decode\) is an error-correcting algorithm with respect to \(G\). If \(Decode\) fails, then return \(\bot\).
\[\text{b) Compute } m' = (mS) \cdot S^{-1}, \text{ parse } m' = (u|m), \text{ where } u \in F_2^k \text{ and } m \in F_{2^k}^n, \text{ and return } m.\]

The scheme described above is CPA-secure in the standard model, assuming the hardness of the DMEc\((n, k, t)\) problem and the DLPN\((k_1, n, B(n, t))\) problem \([27],[62]\). We now recall these two problems.

Definition 2 (The Decisional McEliece problem): The DMEc\((n, k, t)\) problem is to distinguish if a given \(G \in F_2^{k \times n}\) is a uniformly random matrix over \(F_2^{k \times n}\) or is generated by ME.KeyGen\((n, k, t)\) above. When \(n = n(\lambda), k = k(\lambda), \text{ and } t = t(\lambda), \text{ the DMEc}(n, k, t) \text{ problem is hard if the success probability of any PPT distinguisher is at most } 1/2^n + \text{negl}(\lambda)\).

Definition 3 (The Decisional Learning Parity with (fixed-weight) Noise problem): The DLPN\((k, n, B(n, t))\) problem, given a pair \((A, v) \in F_2^{k \times n} \times F_2^n\), is to distinguish whether \((A, v)\) is a uniformly random pair over \(F_2^{k \times n} \times F_2^n\) or is obtained by choosing \(A \leftarrow F_2^{k \times n}, u \leftarrow F_2^k, e \leftarrow \mathcal{B}(n, t)\) and outputting \((A, u \cdot A + e)\). When \(k = k(\lambda), n = n(\lambda), \text{ and } t = t(\lambda), \text{ the DLPN}(k, n, B(n, t)) \text{ problem is hard if the success probability of any PPT distinguisher is at most } 1/2^n + \text{negl}(\lambda)\).

B. Group Signatures

We follow the definition of group signatures provided in \([14]\) for the case of static groups.

Definition 4: A group signature
\[
\mathcal{GS} = (\text{KeyGen, Sign, Verify, Open})
\]
is a tuple of the following four polynomial-time algorithms.

1) KeyGen: This randomized algorithm takes as input \((1^\lambda, 1^N)\), where \(N \in \mathbb{N}\) is the number of group users, and outputs \((gpk, gmsk, gsk)\), where \(gpk\) is the group public key, \(gmsk\) is the group manager’s secret key, and \(gsk = \{gsk[j]\}_{j \in [0, N-1]}\) with \(gsk[j]\) being the secret key for the group user of index \(j\).

2) Sign: This randomized algorithm takes as input a secret signing key \(gsk[j]\) for some \(j \in [0, N-1]\) and a message \(M\) and returns a group signature \(\Sigma\) on \(M\).

3) Verify: This deterministic algorithm takes as input the group public key \(gpk\), a message \(M\), and a signature \(\Sigma\) on \(M\). The output is either 1 (Accept) or 0 (Reject).

4) Open: This deterministic algorithm takes as input the group manager’s secret key \(gmsk\), a message \(M\), and a signature \(\Sigma\) on \(M\). It outputs either \(j \in [0, N-1]\), which is an index associated with a particular user, or \(\bot\), indicating failure.

A correct group signature scheme requires that, for all \(\lambda, N \in \mathbb{N}\), all \((gpk, gmsk, gsk)\) produced by KeyGen\((1^\lambda, 1^N)\), all \(j \in [0, N-1]\), and all messages \(M \in \{0, 1\}^n\), we have
\[
\text{Verify}(gpk, M, \text{Sign}(gsk[j], M)) = 1 \text{ and Open}(gmsk, M, \text{Sign}(gsk[j], M)) = j.
\]

A secure group signature scheme must meet two conditions.

1) Traceability: all signatures, even those produced by a coalition of group users and the group manager, can be traced back to a member of the coalition.

2) Anonymity: signatures generated by two distinct group users are computationally indistinguishable to an adversary who knows all of the user secret keys. In Bellare et al.’s model \([14]\), the anonymity adversary is granted access to an opening oracle (CCA-anonymity). A relaxed notion, where the adversary cannot query the opening oracle (CPA-anonymity), was later proposed by Boneh et al. \([4]\).

We now give the formal definitions of CPA-anonymity, CCA-anonymity and traceability.

Definition 5: A group signature \(\mathcal{GS}\) is CPA-anonymous if, for all polynomial \(N(\cdot)\) and any PPT adversaries \(\mathcal{A}\), the advantage of \(\mathcal{A}\) in the following experiment is negligible in \(\lambda\).

1) Run \((gpk, gmsk, gsk) \leftarrow \text{KeyGen}(1^\lambda, 1^N)\) and then, send \((gpk, gsk)\) to \(\mathcal{A}\).

2) \(\mathcal{A}\) outputs two identities \(j_0, j_1 \in [0, N-1]\) with a message \(M^*\). Choose a random bit \(b\) and give \(\Sigma^* \leftarrow \text{Sign}(gsk[j_b], M^*)\) to \(\mathcal{A}\). Then, \(\mathcal{A}\) outputs a bit \(b^*\).

If \(b^* = b\), then \(\mathcal{A}\) succeeds. The advantage of \(\mathcal{A}\) is defined to be \(\Pr[\mathcal{A}\text{ succeeds}] - \frac{1}{2}\).

A group signature \(\mathcal{GS}\) is CCA-anonymous if for all polynomial \(N(\cdot)\) and any PPT adversaries \(\mathcal{A}\), the advantage of \(\mathcal{A}\) in the following experiment is negligible in \(\lambda\).

1) Run \((gpk, gmsk, gsk) \leftarrow \text{KeyGen}(1^\lambda, 1^N)\) and send \((gpk, gsk)\) to \(\mathcal{A}\).

2) \(\mathcal{A}\) can make queries to the opening oracle. On input a message \(M\) and a signature \(\Sigma\), the oracle returns \(\text{Open}(gmsk, M, \Sigma)\) to \(\mathcal{A}\).

3) \(\mathcal{A}\) outputs two identities \(j_0, j_1 \in [0, N-1]\) with a message \(M^*\). Choose a random bit \(b\) and give \(\Sigma^* \leftarrow \text{Sign}(gsk[j_b], M^*)\) to \(\mathcal{A}\).

4) \(\mathcal{A}\) can make further queries to the opening oracle, with the exception that it cannot query for the opening of \((M^*, \Sigma^*)\).

5) Finally, \(\mathcal{A}\) outputs a bit \(b^*\).

\(\mathcal{A}\) succeeds if \(b^* = b\). The advantage of \(\mathcal{A}\) is defined to be \(\Pr[\mathcal{A}\text{ succeeds}] - \frac{1}{2}\).

A group signature \(\mathcal{GS} = (\text{KeyGen, Sign, Verify, Open})\) is traceable if, for all polynomial \(N(\cdot)\) and any PPT adversaries
We have $i \in T$ and $\lambda = (1, j)$, respectively.

Before describing the protocols, we introduce several supporting notions and techniques. Let $\ell$ be a positive integer and $N = 2^\ell$. For $x = (x_0, x_1, \ldots, x_{N-1}) \in \mathbb{F}_2^N$ and for $j \in [0, N-1]$, we write $x = \delta_j^{N}$ if $x_j = 1$ and $x_j = 0$ for all $i \neq j$. An encoding function $\text{Encode} : [0, N-1] \rightarrow \mathbb{F}_2^\ell$ maps an integer $j \in [0, N-1]$, whose binary representation is $I2B(j) = (j_0, \ldots, j_{\ell-1})$, to the vector $\text{Encode}(j) = (1 - j_0, j_0, \ldots, 1 - j_{\ell-1}, j_{\ell-1})$.

Given a vector $b = (b_0, \ldots, b_{\ell-1}) \in \{0, 1\}^\ell$, we define two permutations. The first permutation $T_b : \mathbb{F}_2^N \rightarrow \mathbb{F}_2^N$ transforms $x = (x_0, \ldots, x_{N-1})$ to $(x'_0, \ldots, x'_{N-1})$, where for each $i \in [0, N-1]$, we have $x_i = x'_i$, with $i' = 2B(I2B(i) + b)$. The second permutation $T'_b : \mathbb{F}_2^{2\ell} \rightarrow \mathbb{F}_2^{2\ell}$ maps 

$$f = (f_0, f_1, \ldots, f_{2\ell-1}) \rightarrow T'_b(f) = (f_0 + b_0, f_1 + b_1, \ldots, f_{2\ell-1} + b_{\ell-1}).$$

Observe that, for any $j \in [0, N-1]$ and any $b \in \{0, 1\}^\ell$, we have

$$x = \delta_j^{N} \iff T_b(x) = \delta_{2B(I2B(j) + b)}^{N}$$

and

$$f = \text{Encode}(j) \iff T'_b(f) = \text{Encode}(2B(I2B(j) + b)).$$

**Example 1:** Given $N = 2^4$ and $j = 6$, we quickly obtain $I2B(j) = (0, 1, 1, 0)$ and $\text{Encode}(j) = (1, 0, 0, 1, 0, 1, 1, 0, 0)$. If $b = (1, 0, 1, 0)$, then $2B(I2B(j) + b) = 2B(1, 1, 0, 0) = 12$. We have $T_b(\delta_6^N) = \delta_{12}^N$ and

$$T'_b(\text{Encode}(6)) = (0, 1, 0, 1, 1, 0, 1, 0, 0) = \text{Encode}(12).$$

### A. The Interactive Protocol Underlying the CPA-Anonymous Group Signature

We now present the interactive zero-knowledge argument of knowledge (ZKAsK) that will be used in the CPA-anonymous group signature scheme of Section IV. Let $n, k, t, m, r, \omega, \ell$ be positive integers, and $N = 2^\ell$. The public input consists of matrices $G \in \mathbb{F}_2^{k \times n}$, $H \in \mathbb{F}_2^{t \times m}$, as well as $N$ syndromes $y_0, \ldots, y_{N-1} \in \mathbb{F}_2^n$, and vector $c \in \mathbb{F}_n^\ell$. The protocol allows the prover $P$ to simultaneously convince the verifier $V$ in zero-knowledge that $P$ possesses a vector $s \in \mathbb{B}(m, \omega)$ corresponding to certain syndrome $y_j \in \{y_0, \ldots, y_{N-1}\}$ with hidden index $j$, and that $c$ is a correct encryption of $I2B(j)$ via the randomized McEliece encryption. Specifically, the secret witness of $P$ is a tuple 

$$(j, s, u, e) \in [0, N-1] \times \mathbb{F}_2^n \times \mathbb{F}_2^m \times \mathbb{F}_2^{\ell}$$

that satisfies

$$H \cdot s^T = y_j^T \quad \text{and} \quad s \in \mathbb{B}(m, \omega),$$

$$\left\{ (u \parallel I2B(j)) \cdot G \oplus e = c \quad \text{and} \quad e \in \mathbb{B}(n, t) \right\}.$$

Let $A = [y_0^T \cdots y_{N-1}^T] \in \mathbb{F}_2^{n \times N}$ and $x = \delta_j^N$. We have $A \cdot x^T = y_j^T$ and rewrite

$$H \cdot x^T = y_j^T = H \cdot s^T \oplus A \cdot x^T = 0.$$}

Let $\hat{G} \in \mathbb{F}_2^{(k+\ell+1) \times n}$ be the matrix obtained from $G \in \mathbb{F}_2^{k \times n}$ by replacing its last $\ell$ rows $g_{k+\ell+1}, \ldots, g_k$ by the $2\ell$ rows $0^n, g_{k+\ell+1}, \ldots, g_{k+\ell+2}$. We then observe that (1) $I2B(j) \cdot \hat{G} = (u \parallel \text{Encode}(j)) \cdot \hat{G}$.

Letting $f = \text{Encode}(j)$, we equivalently rewrite (5) as

$$H \cdot f^T \oplus A \cdot x^T = 0 \quad \text{and} \quad x = \delta_j^N \quad \text{and} \quad s \in \mathbb{B}(m, \omega),$$

$$\left\{ (u \parallel f) \cdot \hat{G} \oplus e = c \quad \text{and} \quad f = \text{Encode}(j) \quad \text{and} \quad e \in \mathbb{B}(n, t) \right\}.$$

To obtain a ZKAsK for relation (7) in Stern’s framework [20], $P$ proceeds as follows.

To prove that $x = \delta_j^N$ and $f = \text{Encode}(j)$ while keeping $j$ secret, $P$ samples a uniformly random vector $b \in \{0, 1\}^\ell$, sends $b_1 = I2B(j) \oplus b$, and shows that

$$T_b(x) = \delta_{2B(b_1)}^N \quad \text{and} \quad T'_b(f) = \text{Encode}(B2I(2B(b_1))).$$

By the equivalences observed in (4) and (5), the verifier will be convinced about the facts to prove. Furthermore, since $b$ essentially acts as a one-time pad, the secret $j$ remains perfectly hidden.

To prove in zero-knowledge that $s \in \mathbb{B}(m, \omega)$, $P$ samples a uniformly random permutation $\pi \in S_m$, and shows that $s = \pi(s) \in \mathbb{B}(m, \omega)$. Similarly, to prove in zero-knowledge that $e \in \mathbb{B}(n, t)$, a uniformly random permutation $\sigma \in S_n$ is employed. Finally, to prove the linear equations in zero-knowledge, $P$ samples uniformly random “masking” vectors $(r_x, r_u, r_e, r_{fx}, r_{fe})$ and shows that

$$H \cdot (s \oplus r_s)^T \oplus A \cdot (x \oplus r_x)^T = H \cdot r_s^T \oplus A \cdot r_x^T$$

and

$$\left\{ (u \parallel r_u) \cdot (f \oplus r_f) \cdot \hat{G} \oplus (e \oplus r_e) \cdot c = (r_u \| r_f) \cdot \hat{G} \oplus r_e \right\}.$$

Now let $\text{COM} : \{0, 1\}^* \rightarrow \{0, 1\}^\lambda$ be a collision-resistant hash function, to be modelled as a random oracle. The prover
and the verifier \( \mathcal{V} \) first perform the preparatory steps described above, and then interact as described in Figure [1].

**Analysis of the Protocol.** The following theorem summarizes the properties of our protocol.

*Theorem 2:* The interactive protocol described in Section III-A has perfect completeness. Its communication cost is bounded above by \( \beta = (N + 3\log N) + m\log m + 1 + n\log n + 1 + k + 5\lambda \) bits. If \( \text{COM} \) is modelled as a random oracle, then the protocol is statistical zero-knowledge. If \( \text{COM} \) is a collision-resistant hash function, then the protocol is an argument of knowledge.

The given interactive protocol is perfectly complete, i.e., if \( \mathcal{P} \) possesses a valid witness \((j,s,u,e)\) and follows the protocol, then \( \mathcal{V} \) always outputs 1. Indeed, given \((j,s,u,e)\) satisfying (6), \( \mathcal{P} \) can always obtain \((j,s,x,u,f,e)\) satisfying (7). Then, as discussed above, the following three assertions hold.

\[
\forall \pi \in S_m : \pi(s) \in B(m, \omega), \\
\forall \sigma \in S_n : \sigma(e) \in B(n, t), \\
\forall b \in \{0,1\}^f : T_b(x) = \delta^N_{2B(12B(j) \oplus b)} = w_x \quad \text{and} \quad T_b(f) = \text{Encode}(2B(12B(j) \oplus b)) = w_f.
\]

Thus, \( \mathcal{P} \) always passes \( \mathcal{V}' \)'s checks when \( \text{Ch} = 1 \). When \( \text{Ch} = 2 \), \( \mathcal{P} \) also passes the verification, since the linear equations in (3) hold true. Finally, for \( \text{Ch} = 3 \), it suffices to note that \( \mathcal{V} \) simply checks for honest computations of \( c_1 \) and \( c_2 \).

Let us now consider the communication cost. The commitment \( \text{CMT} \) has bit-size \( 3\lambda \). If \( \text{Ch} = 1 \), then the response \( \text{RSP} \) has bit-size

\[3\ell + N + 2(m + n + \lambda).\]

If \( \text{Ch} = 2 \) or \( \text{Ch} = 3 \), then \( \text{RSP} \) has bit-size

\[2\ell + N + m\log m + 1 + n\log n + 1 + k + 2\lambda.\]

Therefore, the protocol’s total communication cost, in bits, is less than the specified bound \( \beta \).

The following lemma says that our interactive protocol is statistically zero-knowledge if \( \text{COM} \) is modelled as a random oracle. It employs the standard simulation technique for Stern-type protocols as was done, e.g., in [20], [63], and [64].

*Lemma 3:* In the random oracle model, there exists an efficient simulator \( \mathcal{S} \) interacting with a (possibly cheating) verifier \( \tilde{\mathcal{V}} \), such that, given only the public input of the protocol, \( \mathcal{S} \) outputs, with probability negligibly close to \( 2/3 \), a simulated transcript that is statistically close to the one produced by the honest prover in the real interaction.

*Proof:* Simulator \( \mathcal{S} \), given the public input \((H, A, G, c)\), begins by selecting a random \( \text{Ch} \in \{1,2,3\} \). This is a prediction of the challenge value that \( \tilde{\mathcal{V}} \) will not choose.

1) **Case \( \text{Ch} = 1 \):** \( \text{S} \) proceeds as follows.

a) Compute \( s' \in F_m^2 \) and \( x' \in F_2^N \) such that \( H \cdot s'^T \oplus A \cdot x'^T = 0 \). Compute \( u' \in F_{2^k-\ell}^2 \), \( f' \in F_{2^j}^j \), \( e' \in F_2^f \) such that \( (u' || f') \cdot G' \oplus e' = c \). These steps can be done efficiently by using linear algebraic tools.

b) Sample uniformly random objects, and send a commitment computed in the same manner as of the real prover. More explicitly, \( S \) samples

\[
\begin{align*}
b &\leftarrow \{0,1\}^f, \\
p &\leftarrow S_m, \quad \sigma \leftarrow S_n, \\
\rho_1, \rho_2, \rho_3 &\leftarrow \{0,1\}^3, \quad r_x \leftarrow F_2^m, \\
r_u &\leftarrow F_2^{2k-\ell}, \quad r_f \leftarrow F_2^{2j}, \quad r_e \leftarrow F_2^f,
\end{align*}
\]

and sends the commitment \( \text{CMT} := (c_1', c_2', c_3') \), where

\[
c_1' = \text{COM}(b, \pi, \sigma, H \cdot r_s^T \oplus A \cdot r_x^T, \\
(r_u || r_f) \cdot G' \oplus r_e; \rho_1),
\]

\[
c_2' = \text{COM}(\pi(r_s), T_b(r_x), T_b(r_f), \sigma(r_e); \rho_2),
\]

\[
c_3' = \text{COM}(\pi(s' \oplus r_s), T_b(x' \oplus r_x), T_b(f' \oplus r_f), \sigma(e' \oplus r_e); \rho_3).
\]

Upon receiving a challenge \( \text{Ch} \) from \( \tilde{\mathcal{V}} \), the simulator responds accordingly.

a) If \( \text{Ch} = 1 \): Output \( \bot \) and abort.

b) If \( \text{Ch} = 2 \): Send

\[
\text{RSP} = (b, \pi, \sigma, s' \oplus r_s, x' \oplus r_x, \\
u' \oplus r_u, f' \oplus r_f, e' \oplus r_e; \rho_1, \rho_3).
\]

c) If \( \text{Ch} = 3 \): Send

\[
\text{RSP} = (b, \pi, \sigma, r_s, r_x, r_u, r_f, r_e; \rho_1, \rho_2).
\]

2) **Case \( \text{Ch} = 2 \):** \( \mathcal{S} \) samples

\[
j' \leftarrow [0, N - 1], \quad s' \leftarrow B(m, \omega), \quad e' \leftarrow B(n, t),
\]

\[
b \leftarrow \{0,1\}^f, \quad \pi \leftarrow S_m, \quad \sigma \leftarrow S_n, \\
\rho_1, \rho_2, \rho_3 \leftarrow \{0,1\}^3, \quad r_x \leftarrow F_2^m, \\
r_u \leftarrow F_2^{2k-\ell}, \quad r_f \leftarrow F_2^{2j}, \quad r_e \leftarrow F_2^f.
\]

It also lets \( x' = \delta^N_{2} \) and \( f' = \text{Encode}(j') \). Then \( \mathcal{S} \) sends the commitment \( \text{CMT} \) computed as in (9).

Upon receiving a challenge \( \text{Ch} \) from \( \tilde{\mathcal{V}} \), it responds as follows.

a) If \( \text{Ch} = 1 \): Send

\[
\text{RSP} = (12B(j') \oplus b, \pi(r_s), \pi(s'), \\
T_b(r_x), T_b(r_f), \sigma(r_e); \rho_2, \rho_3).
\]

b) If \( \text{Ch} = 2 \): Output \( \bot \) and abort.

c) If \( \text{Ch} = 3 \): Send \( \text{RSP} \) computed as in the case (\( \text{Ch} = 1, \text{Ch} = 3 \)).

3) **Case \( \text{Ch} = 3 \):** The simulator performs the preparation as in the case \( \text{Ch} = 2 \) above as well as samples \( u' \sim F_{2^k-\ell}^2 \).

It then sends the commitment \( \text{CMT} := (c_1', c_2', c_3') \), where \( c_2, c_3 \) are computed as in (9) and

\[
c_1' = \text{COM}(b, \pi, \sigma, H \cdot (s' \oplus r_s)^T \oplus A \cdot (x' \oplus r_x)^T, \\
(u' \oplus r_u || f' \oplus r_f) \cdot G' \oplus (e' \oplus r_e) \oplus c; \rho_1).
\]
1) **Commitment:** $\mathcal{P}$ samples the uniformly random objects

$$b \overset{\$}{\leftarrow} \{0,1\}^\ell, \pi \overset{\$}{\leftarrow} S_m, \sigma \overset{\$}{\leftarrow} S_n, \rho_1, \rho_2, \rho_3 \overset{\$}{\leftarrow} \{0,1\}^\lambda, r_s \overset{\$}{\leftarrow} \mathbb{F}_m^n, r_x \overset{\$}{\leftarrow} \mathbb{F}_2^n, r_u \overset{\$}{\leftarrow} \mathbb{F}_{2^\ell}, r_f \overset{\$}{\leftarrow} \mathbb{F}_{2^\ell}, e \overset{\$}{\leftarrow} \mathbb{F}_{2^\ell}.$$ 

It then sends the commitment $CMT := (c_1, c_2, c_3)$ to $\mathcal{V}$, where

$$c_1 = \text{COM}(b, \pi, \sigma, H \cdot r_x^T \oplus A \cdot r_x, (r_u \parallel r_f) \cdot \tilde{G} \oplus e; \rho_1),$$
$$c_2 = \text{COM}(\pi r_s, T_b(r_x), T'_b(r_f), \sigma; \rho_2),$$
$$c_3 = \text{COM}(\pi (s \oplus r_s), T_b(x \oplus r_x), T'_b(f \oplus r_f), \sigma(e \oplus e; \rho_3).$$

2) **Challenge:** Upon receiving $CMT$, $\mathcal{V}$ sends a challenge $Ch \overset{\$}{\leftarrow} \{1, 2, 3\}$ to $\mathcal{P}$.

3) **Response:** $\mathcal{P}$ responds based on $Ch$.

a) If $Ch = 1$: Reveal $c_2$ and $c_3$. Let

$$b_1 = 12B(j) \oplus b, v_s = \pi(r_s), v_x = T_b(r_x), v_f = T'_b(r_f), v_e = \sigma(e), \text{ and } w_e = \sigma(e).$$

Send RSP := $(b_1, v_s, w_s, v_x, v_f, v_e, w_e; \rho_2, \rho_3)$ to $\mathcal{V}$.

b) If $Ch = 2$: Reveal $c_1$ and $c_3$. Let

$$b_2 = b, \pi_2 = \pi, \tau_2 = \tau, \sigma_2 = \sigma, \mu_0 = s \oplus r_s, \mu_2 = x \oplus r_x, \mu_f = f \oplus r_f, \text{ and } w_e = e \oplus e.$$ 

Send RSP := $(b_2, \pi_2, \sigma_2, \mu_0, \mu_2, \mu_f; \rho_3)$ to $\mathcal{V}$.

c) If $Ch = 3$: Reveal $c_1$ and $c_2$. Let

$$b_3 = b, \pi_3 = \pi, \sigma_3 = \sigma, y_s = r_s, y_x = r_x, y_u = r_u, y_f = r_f, \text{ and } y_e = e.$$ 

Send RSP := $(b_3, \pi_3, \sigma_3, y_s, y_x, y_u, y_f, y_e; \rho_1)$ to $\mathcal{V}$.

4) **Verification:** Upon receiving RSP, $\mathcal{V}$ proceeds based on $Ch$.

a) If $Ch = 1$: Let $w_x = \delta_{B2l(b_1)}^N \in \mathbb{F}_{2^\ell}^N$ and $w_f = \text{Encode}(B2l(b_1)) \in \mathbb{F}_{2^\ell}^N$.

Check that $w_s \in B(m, \omega), w_e \in B(n, t)$,

$$c_2 = \text{COM}(v_s, v_x, v_f, v_e; \rho_2), \text{ and } c_3 = \text{COM}(v_s \oplus w_s, v_x \oplus w_x, v_f \oplus w_f, v_e \oplus w_e; \rho_3).$$

b) If $Ch = 2$: Check that

$$c_1 = \text{COM}(b_2, \pi_2, \tau_2, H \cdot z_x^T \oplus A \cdot z_x^T, (z_u \parallel z_f) \cdot \tilde{G} \oplus e; \mu_1) \text{ and }$$
$$c_3 = \text{COM}(\pi_2(z_s), T_{b_2}(z_x), T'_b(z_f), \sigma; \rho_3).$$

c) If $Ch = 3$: Check that

$$c_1 = \text{COM}(b_3, \pi_3, \sigma_3, H \cdot y_x^T \oplus A \cdot y_x^T, (y_u \parallel y_f) \cdot \tilde{G} \oplus y_e; \rho_1) \text{ and }$$
$$c_2 = \text{COM}(\pi_3(y_s), T_{b_3}(y_x), T'_b(y_f), \sigma; \rho_2).$$

In each case, $\mathcal{V}$ outputs 1 if and only if all of the conditions hold. Otherwise, $\mathcal{V}$ outputs 0.

**Fig. 1:** The underlying ZK protocol of the CPA-anonymous group signature.

Upon receiving a challenge $Ch$ from $\tilde{\mathcal{V}}$, it responds as follows.

a) If $Ch = 1$: Send RSP computed as in the case $(Ch = 2, Ch = 1)$.

b) If $Ch = 2$: Send RSP computed as in the case $(Ch = 1, Ch = 2)$.

c) If $Ch = 3$: Output $\bot$ and abort.

In every case that we have considered above, the distribution of the commitment $CMT$ and the distribution of the challenge $Ch$ from $\mathcal{V}$ are statistically close to those in the real interaction, since the outputs of the random oracle COM are assumed to be uniformly random. Hence, the probability that $\mathcal{S}$ outputs $\bot$ is negligibly close to $1/3$. Moreover, one can check that whenever the simulator does not abort, it provides a successful transcript, whose distribution is statistically close to that of the prover in the real interaction. We have thus constructed a simulator that can successfully impersonate the honest prover, with probability $2/3$. \hfill $\blacksquare$

The next lemma establishes that our protocol satisfies the special soundness property of $\Sigma$-protocols. This implies, as had been shown in [63], that the protocol is indeed an argument of knowledge.

**Lemma 4:** Let COM be a collision-resistant hash function. Given the public input of the protocol, a commitment $CMT$ and three valid responses RSP$_1$, RSP$_2$, RSP$_3$ to all three possible values of the challenge $Ch$, one can efficiently construct a knowledge extractor $\mathcal{E}$ that outputs a tuple $(j', s', u', e') \in \{0, N - 1\} \times \mathbb{F}_m^n \times \mathbb{F}_{2^\ell}^{n} \times \mathbb{F}_{2^\ell}$ that simultaneously satisfies

$$H \cdot s'^T = y_j^T, s' \in B(m, \omega), (u' \parallel 12B(j')) \cdot G \oplus e' = c, \text{ and } e' \in B(n, t).$$
Proof: Assume that we have CMT = (c₁, c₂, c₃) and the three responses

\[ \text{RSP}_1 = (b_1, v_s, w_s, v_x, v_f, e_v, w_e; \rho_2, \rho_3), \]
\[ \text{RSP}_2 = (b_2, \pi_2, \sigma_2, z_s, z_x, z_f, e_z; \rho_1, \rho_3), \]
\[ \text{RSP}_3 = (b_3, \pi_3, \sigma_3, y_s, y_x, y_u, y_f, e_y; \rho_1, \rho_2), \]

that satisfy all of the verification conditions when Ch = 1, Ch = 2, and Ch = 3, respectively. More explicitly, we have

\[ w_s \in B(m, \omega), \quad w_x = \delta^N_{\text{B2l}(b_1)}, \]
\[ w_f = \text{Encode}(\text{B2l}(b_1)), \quad w_e \in B(n, t), \]
\[ c_1 = \text{COM}(b_2, \pi_2, \sigma_2, H \cdot z_u^T \oplus A \cdot z_x^T, (z_u \parallel z_f) \cdot \hat{G} \oplus e_z \oplus c; \rho_1), \]
\[ = \text{COM}(b_2, \pi_2, \sigma_2, H \cdot y_u^T \oplus A \cdot y_x^T, (y_u \parallel y_f) \cdot \hat{G} \oplus e_y \oplus c; \rho_1), \]
\[ c_2 = \text{COM}(v_s, v_x, v_f, e_v; \rho_2), \]
\[ = \text{COM}(v_s, v_x, v_f, w_x, v_f, v_f, w_f, v_e \oplus w_e; \rho_3), \]
\[ c_3 = \text{COM}(\pi_3, \sigma_3, H \cdot y_u^T \oplus A \cdot y_x^T, (y_u \parallel y_f) \cdot \hat{G} \oplus e_y \oplus c; \rho_1), \]

Based on the collision-resistance property of COM, we infer

\[ b_2 = b_3, \quad \pi_2 = \pi_3, \quad \sigma_2 = \sigma_3, \]
\[ \delta^N_{\text{B2l}(b_1)} = w_x = T_{b_2}(z_u) + T_{b_2}(y_k) = T_{b_2}(z_x + y_x), \]
\[ \text{Encode}(\text{B2l}(b_1)) = w_f = T_{b_2}(z_f) + T_{b_2}(y_f) \]
\[ = T_{b_2} \cdot (z_f \oplus y_f), \]
\[ B(m, \omega) \ni w_s = \pi_2(z_s) + \pi_1(y_s) = \pi_2(z_x + y_x), \]
\[ B(n, t) \ni w_e = \sigma_2(z_e) + \sigma_3(y_e) = \sigma_2(z_x \oplus y_e), \]
\[ H \cdot (z_u \oplus y_u)^T \oplus A \cdot (z_x \oplus y_x)^T = 0, \]
\[ (z_u \parallel y_u) \cdot T_{b_2} \cdot \hat{G} \oplus e_y = c. \]

Letting

\[ j' = \text{B2l}(b_1 + b_2) \in [0, N - 1] \text{ and } x' = z_x + y_x \in \mathbb{F}_2^N, \]

we derive \( x' = \delta^N \) by using (4). Thus, \( A \cdot x'^T = y_x^T \). Let \( f' = z_f \oplus y_f \in \mathbb{F}_2^N \). Then, by (5), we have \( f' = \text{Encode}(j') \).

Let \( s' = z_u \parallel y_u \in \mathbb{F}_2^m \). We have \( s' = \pi_2^{-1}(w_s) \in B(m, \omega) \).

Let \( e' = z_e \parallel y_e \in \mathbb{F}_2^n \). We get \( e' = \sigma_2^{-1}(w_e) \in B(n, t) \).

Let \( u' = z_u \parallel y_u \in \mathbb{F}_2^{k - t} \). Furthermore, we obtain

\[ H \cdot s'^T \oplus A \cdot x'^T = 0 \text{ and } (u' \parallel \text{Encode}(j')) \cdot \hat{G} \oplus e' = c. \]

They imply, respectively, that

\[ H \cdot s'^T = A \cdot x'^T = y_x^T \text{ and } (u' \parallel \text{B2l}(j')) \cdot \hat{G} \oplus e' = c. \]

We have thus constructed an efficient extractor \( \mathcal{E} \) that outputs

\[ (j', s', u', e') \in [0, N - 1] \times \mathbb{F}_2^m \times \mathbb{F}_2^{k - t} \times \mathbb{F}_2^n, \]

satisfying

\[ H \cdot s'^T = y_x^T, \quad s' \in B(m, \omega), \]
\[ (u' \parallel \text{B2l}(j')) \cdot \hat{G} \oplus e' = c, \text{ and } e' \in B(n, t). \]

This completes the proof. 

B. The Interactive Protocol Underlying the CCA-Anonymous Group Signature

The required ZK protocol for our CCA-anonymous group signature scheme of Section [V] is a simple extension of the one underlying the CPA-anonymous group signature that we have described in Section [III-A]. Here, we handle two ciphertexts \( c^{(1)} \) and \( c^{(2)} \) of \( 2B(j) \) by executing two instances of the techniques used for handling one ciphertext \( c \) from Section [III-A].

Applying the same transformations as in Section [III-A], we can translate the statement to be proved to proving knowledge of \( s, x, \{u^{(i)}\}_{i \in [2]}, f, \{e^{(i)}\}_{i \in [2]} \) such that

\[ H \cdot s^T \oplus A \cdot x^T = 0, \quad x = \delta^N, \quad s \in B(m, \omega), \]
\[ \{u^{(i)} \parallel f\} \cdot \hat{G}^{(i)} \oplus e^{(i)} = c^{(i)} \quad \forall i \in [2], \quad f = \text{Encode}(j), \]
\[ \{e^{(i)} \in B(n, t)\}_{i \in [2]}. \]

for public input \((H, A, \hat{G}^{(1)}, \hat{G}^{(2)}, c^{(1)}, c^{(2)})\).

A ZK argument for the obtained equivalent statement can then be obtained in Stern’s framework, using the same permutation and masking techniques of Section [III-A]. The resulting interactive protocol is described in Fig. 2, where COM is a collision-resistant hash function modelled as a random oracle. The protocol is a statistical ZKAoK. Its simulator and extractor are constructed in the same manner as for the protocol in Section [III-A]. The details can therefore be safely omitted here.

IV. A CPA-ANONYMOUS CODE-BASED GROUP SIGNATURE

This section discusses our basic scheme that achieves CPA-anonymity. We start with a description of the scheme and end with the evaluation of its properties.

A. Description, Efficiency, and Correctness of the Scheme

Our group signature scheme consists of the following four algorithms.

1) KeyGen(1^λ, 1^N): On input a security parameter \( \lambda \) and an expected number of group users \( N = 2^t \) poly(\( \lambda \)), for some positive integer \( t \), this algorithm first selects the following parameters and hash functions.

a) Parameters \( n = n(\lambda), k = k(\lambda), t = t(\lambda) \) for a binary \( [n, k, 2t + 1] \) Goppa code.

b) Parameters \( m = m(\lambda), r = r(\lambda), \omega = \omega(\lambda) \) for the Syndrome Decoding problem, such that

\[ r \leq \log \left( \frac{m}{w} \right) - 2\lambda - \mathcal{O}(1). \]

2) Two collision-resistant hash functions, to be modelled as random oracles:

i) \( \text{COM} : \{0, 1\}^* \rightarrow \{0, 1\}^\lambda \) to generate zero-knowledge arguments.

ii) \( \mathcal{H} : \{0, 1\}^* \rightarrow \{1, 2, 3\}^\kappa \), where \( \kappa = \omega \cdot \log \lambda \), for the Fiat-Shamir transformation.

The algorithm then performs the following steps.

a) Run \( \text{ME.KeyGen}(n, k, t) \) to obtain a key pair \( (pk_{\text{ME}} = G \in \mathbb{F}_2^{k \times n}, sk_{\text{ME}}) \) for the randomized McEliece
1) **Commitment:** $\mathcal{P}$ samples the following uniformly random objects.

\[
\begin{align*}
    b & \overset{\$}{\leftarrow} \{0, 1\}, \\
    \pi & \overset{\$}{\leftarrow} \mathbb{S}_m, \\
    \sigma^{(1)}, \sigma^{(2)} & \overset{\$}{\leftarrow} \mathbb{S}_n, \\
    \rho_1, \rho_2, \rho_3 & \overset{\$}{\leftarrow} \{0, 1\}, \\
    r_s & \overset{\$}{\leftarrow} \mathbb{F}_{2^m}, \\
    r_x & \overset{\$}{\leftarrow} \mathbb{F}_n, \\
    r^{(1)}, r^{(2)} & \overset{\$}{\leftarrow} \mathbb{F}_{2^k - \ell}, \\
    r_f & \overset{\$}{\leftarrow} \mathbb{F}_{2^m}, \\
    \tau^{(1)}, \tau^{(2)} & \overset{\$}{\leftarrow} \mathbb{F}_n.
\end{align*}
\]

It then sends the commitment $\text{CMT} := (c_1, c_2, c_3)$ to $\mathcal{V}$, where

\[
\begin{align*}
    c_1 &= \text{COM}\left(b, \pi, \{\sigma^{(i)}\}_{i \in [2]}, H \cdot r^{(1)}_s + A \cdot r^{(1)}_x, \{(r^{(i)}_u || r_f) \cdot \hat{G}^{(i)} \oplus r^{(i)}_e\}_{i \in [2]}; \ \rho_1\right), \\
    c_2 &= \text{COM}\left(\pi(r_s), T_b(r_x), T'_b(r_f), \{\sigma^{(i)}(r^{(i)}_e)\}_{i \in [2]}; \ \rho_2\right), \\
    c_3 &= \text{COM}\left(\pi(s \oplus r_s), \pi(s \oplus r_x), T'_b(f \oplus r_f), \{\sigma^{(i)}(e^{(i)} \oplus r^{(i)}_e)\}_{i \in [2]}; \ \rho_3\right).
\end{align*}
\]

2) **Challenge:** Upon receiving $\text{CMT}$, $\mathcal{V}$ sends a challenge $\text{Ch} \overset{\$}{\leftarrow} \{1, 2, 3\}$ to $\mathcal{P}$.

3) **Response:** $\mathcal{P}$ responds accordingly.

   a) If $\text{Ch} = 1$: Reveal $c_2$ and $c_3$. Let $b_1 = 2B(j) \oplus b$,

   \[
   \begin{align*}
   v_s &= \pi(r_s), \\
   w_s &= \pi(s), \\
   v_x &= T_b(r_x), \\
   v_f &= T'_b(r_f), \\
   \{v^{(i)}_u = \sigma^{(i)}(r^{(i)}_e)\}_{i \in [2]}, \\
   \{w^{(i)}_e = \sigma^{(i)}(e^{(i)})\}_{i \in [2]}. \\
   \end{align*}
   \]

   Send RSP := \((b_1, v_s, w_s, v_x, v_f; \{v^{(i)}_u, w^{(i)}_e\}_{i \in [2]}; \ \rho_2, \rho_3)\) to $\mathcal{V}$.

   b) If $\text{Ch} = 2$: Reveal $c_1$ and $c_3$. Let

   \[
   \begin{align*}
   b_2 &= b, \\
   \pi_2 &= \pi, \\
   \{\sigma^{(i)}_2 = \sigma^{(i)}\}_{i \in [2]}, \\
   z_s &= s \oplus r_s, \\
   z_x &= x \oplus r_x, \\
   \{z^{(i)}_u = u^{(i)} \oplus r^{(i)}_u\}_{i \in [2]}, \\
   \{z^{(i)}_e = e^{(i)} \oplus r^{(i)}_e\}_{i \in [2]}. \\
   \end{align*}
   \]

   Send RSP := \((b_2, \pi_2, \{\sigma^{(i)}_2\}_{i \in [2]}, z_s, z_x, \{z^{(i)}_u\}_{i \in [2]}, z_f, \{z^{(i)}_e\}_{i \in [2]}; \ \rho_1, \rho_3)\) to $\mathcal{V}$.

   c) If $\text{Ch} = 3$: Reveal $c_1$ and $c_2$. Let $b_3 = b$,

   \[
   \begin{align*}
   \pi_3 &= \pi, \\
   \{\sigma^{(i)}_3 = \sigma^{(i)}\}_{i \in [2]}, \\
   y_s &= r_s, \\
   y_x &= r_x, \\
   \{y^{(i)}_u = r^{(i)}_u\}_{i \in [2]}, \\
   y_f &= r_f, \\
   \{y^{(i)}_e = r^{(i)}_e\}_{i \in [2]}. \\
   \end{align*}
   \]

   Send RSP := \((b_3, \pi_3, \{\sigma^{(i)}_3\}_{i \in [2]}, y_s, y_x, \{y^{(i)}_u\}_{i \in [2]}, y_f, \{y^{(i)}_e\}_{i \in [2]}; \ \rho_1, \rho_2)\) to $\mathcal{V}$.

4) **Verification:** Upon receiving RSP, $\mathcal{V}$ proceeds as follows.

   a) If $\text{Ch} = 1$: Let $w_s = \delta_{B2I(b_1)}^{N} \in \mathbb{F}_{2^m}$ and $w_f = \text{Encode}(B2I(b_1)) \in \mathbb{F}_{2^m}$.

   Check that $w_s \in B(m, \omega)$ and $\{w^{(i)}_e \in B(n, t)\}_{i \in [2]}$, and that

   \[
   \begin{align*}
   c_2 &= \text{COM}\left(v_s, v_x, v_f; \{v^{(i)}_u\}_{i \in [2]}; \ \rho_2\right) \text{ and} \\
   c_3 &= \text{COM}\left(v_s \oplus w_s, v_x \oplus w_x, v_f \oplus w_f; \{v^{(i)}_u \oplus w^{(i)}_e\}_{i \in [2]}; \ \rho_3\right).
   \end{align*}
   \]

   b) If $\text{Ch} = 2$: Check that

   \[
   \begin{align*}
   c_1 &= \text{COM}\left(b_2, \pi_2, \{\sigma^{(i)}_2\}_{i \in [2]}, H \cdot z_s \oplus A \cdot z_x, \{(z^{(i)}_u || z_f) \cdot \hat{G}^{(i)} \oplus z^{(i)}_e \oplus e^{(i)}\}_{i \in [2]}; \ \rho_1\right), \\
   c_3 &= \text{COM}\left(\pi_2(z_s), T_b(z_x), T'_b(z_f), \{\sigma^{(i)}_3(z^{(i)}_e)\}_{i \in [2]}; \ \rho_3\right).
   \end{align*}
   \]

   c) If $\text{Ch} = 3$: Check that

   \[
   \begin{align*}
   c_1 &= \text{COM}\left(b_3, \pi_3, \{\sigma^{(i)}_3\}_{i \in [2]}, H \cdot y_s \oplus A \cdot y_x, \{(y^{(i)}_u || y_f) \cdot \hat{G}^{(i)} \oplus y^{(i)}_e\}_{i \in [2]}; \ \rho_1\right), \\
   c_2 &= \text{COM}\left(\pi_3(y_s), T_b(y_x), T'_b(y_f), \{\sigma^{(i)}_3(y^{(i)}_e)\}_{i \in [2]}; \ \rho_2\right).
   \end{align*}
   \]

In each case, $\mathcal{V}$ outputs 1 if and only if all the conditions hold. Otherwise, $\mathcal{V}$ outputs 0.

Fig. 2: The underlying ZK protocol of the CCA-anonymous group signature.
encryption scheme with respect to a binary $[n, k, 2t+1]$ Goppa code. The plaintext space is $F_2^n$.

b) Choose a matrix $H \in F_2^{s \times m}$.

c) For each $j \in [0, N - 1]$, pick $s_j \leftarrow B(m, \omega)$ and let $y_j \in F_2^s$ be its syndrome, i.e., $y_j^T = H \cdot s_j^T$.

d) Output

\[
\begin{align*}
gpk & = (G, H, y_0, \ldots, y_{N-1}), \
gsk & = sk_{ME}, \\
& \text{gsk} = (s_0, \ldots, s_{N-1}). \tag{11}
\end{align*}
\]

2) Sign($gsk[j], M$): To sign a message $M \in \{0, 1\}^*$ under $gpk$, the group user of index $j$, who possesses secret key $s = gsk[j]$, performs the following steps.

a) Encrypt the binary representation of $j$, i.e., $I2B(j) \in F_2^s$, under the randomized McEliece encryption key $G$.

This is done by sampling $(u \leftarrow F_2^{k-t}, e \leftarrow B(n, t))$ and outputting the ciphertext

\[
c = (u \parallel I2B(j)) \cdot G \oplus e \in F_2^n.
\]

b) Generate a NIZKAoK $\Pi$ to simultaneously prove, in zero-knowledge, the possession of an $s \in B(m, \omega)$ corresponding to a certain syndrome $y_j \in \{y_0, \ldots, y_{N-1}\}$ with hidden index $j$, and that $c$ is a correct McEliece encryption of $I2B(j)$. This is done by employing the interactive argument system in Section III-A with public input $(G, H, y_0, \ldots, y_{N-1}, c)$, and prover’s witness $(j, s, u, e)$ that satisfies

\[
H \cdot s^T = y_j^T, \quad s \in B(m, \omega), \\
(u \parallel I2B(j)) \cdot G \oplus e = c, \quad e \in B(n, t). \tag{12}
\]

The protocol is repeated $\kappa = \omega \cdot \log \lambda$ times to achieve negligible soundness error, before being made non-interactive by using the Fiat-Shamir heuristic. We have

\[
\Pi = \{\text{CMT}^{(1)}, \ldots, \text{CMT}^{(\kappa)}; (\text{Ch}^{(1)}, \ldots, \text{Ch}^{(\kappa)}) ; \\
\text{RSP}^{(1)}, \ldots, \text{RSP}^{(\kappa)}\}, \tag{13}
\]

where $(\text{Ch}^{(1)}, \ldots, \text{Ch}^{(\kappa)})$ is given by

\[
\mathcal{H}(M; \text{CMT}^{(1)}, \ldots, \text{CMT}^{(\kappa)}; \text{gpk}, c) \in \{1, 2, 3\}^\kappa.
\]

c) Output the group signature $\Sigma = (c, \Pi)$.

3) Verify($gpk, M, \Sigma$): Parse $\Sigma$ as $(c, \Pi)$, parse $\Pi$ as in (13), and then proceed as follows.

a) Return 0 if

\[
(\text{Ch}^{(1)}, \ldots, \text{Ch}^{(\kappa)}) \notin \mathcal{H}(M; \text{CMT}^{(1)}, \ldots, \text{CMT}^{(\kappa)}; \text{gpk}, c).
\]

b) For $i = 1$ to $\kappa$, run the verification step of the interactive protocol in Section III-A on the public input $(G, H, y_0, \ldots, y_{N-1}, c)$ to check if $\text{RSP}^{(i)}$ is valid with respect to $\text{CMT}^{(i)}$ and $\text{Ch}^{(i)}$. Return 0 if any of the verification conditions fails to hold.

c) Return 1.

4) Open($gmsk, M, \Sigma$): Parse $\Sigma$ as $(c, \Pi)$ and running $\text{ME.Dec}(gmsk, c)$. Return $\bot$ if decryption fails.

Return $j = B2l(g) \in [0, N - 1]$ if decryption outputs $g \in F_2^n$.

Remark 1: Lemma 1 assures us that, for the parameters $m, r, \omega$ that satisfy the inequality condition in (10), the distribution of syndrome $y_j$, for all $j \in [0, N - 1]$, is statistically close to the uniform distribution over $F_2^n$.

The efficiency, correctness, and security aspects of the above group signature scheme can now be summarized into the following theorem.

Theorem 5: The given group signature scheme is correct. The public key has size $nk + (m + N)r$ bits. The bit-size of the signatures is bounded above by $(N + 3 \log N + m \log m + 1) + n \log n + 1 + k + 5\lambda)k + n$. In the random oracle model we can make two further assertions. First, if the Decisional McEliece problem DMcE($n, k, t$) and the Decisional Learning Parity with fixed-weight Noise problem DLPN($k - t, n, B(n, t)$) are hard, then the scheme is CPA-anonymous. Second, if the Syndrome Decoding problem SD($m, r, \omega$) is hard, then the scheme is traceable.

In terms of efficiency, it is clear from (11) that $gpk$ has bit-size $nk + (m + N)r$. The length of the NIZKAoK $\Pi$ is times the communication cost of the underlying interactive protocol. Thus, by Theorem 2, $\Sigma = (c, \Pi)$ has bit-size bounded above by $(N + 3 \log N + m \log m + 1 + n \log n + 1 + k + 5\lambda)k + n$.

To see that the given group signature scheme is correct, observe that the honest user with index $j$, for any $j \in [0, N - 1]$, can always obtain a tuple $(j, s, u, e)$ satisfying (12). Then, since the underlying interactive protocol is perfectly complete, $\Pi$ is a valid NIZKAoK and algorithm Verify($gpk, M, \Sigma$) always outputs 1, for any message $M \in \{0, 1\}^*$. On the correctness of Open, it suffices to note that, if the ciphertext $c$ is of the form $c = (u \parallel I2B(j)) \cdot G \oplus e$, where $e \in B(n, t)$, then, by the correctness of the randomized McEliece encryption scheme, ME.Dec($gmsk, c$) outputs $I2B(j)$.

B. Anonymity

Let $A$ be any PPT adversary attacking the CPA-anonymity of the scheme with advantage $\epsilon$. We will prove $\epsilon = \text{negl}(\lambda)$ based on the ZK property of the underlying argument system. To do so, we retain the assumed hardness of the DMcE($n, k, t$) and the DLPN($k - t, n, \text{B}(n, t)$) problems. Specifically, we consider the following sequence of hybrid experiments $G_0^{(b)}, G_1^{(b)}, G_2^{(b)}, G_3^{(b)},$ and $G_4$.

Experiment $G_0^{(b)}$. This is the real CPA-anonymity game. The challenger runs $\text{KeyGen}(1^\lambda, 1^N)$ to obtain

\[
\{(gpk = (G, H, y_0, \ldots, y_{N-1}), gmsk = sk_{ME}, \\
gsk = (gsk[0], \ldots, gsk[N - 1])\},
\]

and sends $gpk$ and $\{gsk[j]\}_{j \in [0, N - 1]}$ to $A$. In the challenge phase, $A$ outputs a message $M^*$ together with two indices $j_0, j_1 \in [0, N - 1]$. The challenger sends back a challenge signature

\[
\Sigma^* = (c^*, \Pi^*) \leftarrow \text{Sign}(gpk, gsk[j_b]),
\]

Note: The symbol $\Sigma$ is used for both the group signature and the challenge signature.
where
\[ c^* = (u \| l2B(j_b)) \cdot G \oplus e, \]
with \( u \leftarrow \mathbb{F}_2^{k-\ell} \) and \( e \leftarrow B(n, t) \). The adversary then outputs \( b \) with probability 1/2 + \( \epsilon \).

**Experiment \( G_2^{(b)} \).** This experiment makes the following change with respect to \( G_1^{(b)} \). The encrypting key \( G \) obtained from ME.KeyGen(\( n, k, t \)) is replaced by a uniformly random matrix \( G \leftarrow \mathbb{F}_2^{n \times k} \). Lemma 6 will demonstrate that Experiments \( G_1^{(b)} \) and \( G_2^{(b)} \) are computationally indistinguishable based on the assumed hardness of the DMCe(\( n, k, t \)) problem.

**Lemma 6:** If \( A \) can distinguish Experiments \( G_1^{(b)} \) and \( G_2^{(b)} \) with probability non-negligibly larger than 1/2, then there exists an efficient distinguisher \( D_1 \) that solves the DMCe(\( n, k, t \)) problem with the same probability.

**Proof:** An instance of the DMCe(\( n, k, t \)) problem is \( G^* \in \mathbb{F}_2^{n \times k} \), which can either be uniformly random or be generated by ME.KeyGen(\( n, k, t \)). The distinguisher \( D_1 \) receives a challenge instance \( G^* \) and uses \( A \) to distinguish between the two. It interacts with \( A \) by performing the following steps.

1. **Setup.** Generate
   \[ (H, y_0, \ldots, y_{N-1}) \text{ and } (gsk[0], \ldots, gsk[N-1]) \]
as in the real scheme. Send \( A \) the pair
   \[ (gpk^* = (G^*, H, y_0, \ldots, y_{N-1}), gsk = (gsk[0], \ldots, gsk[N-1])) \].

2. **Challenge.** Upon receiving the challenge \( (M^*, j_0, j_1) \), \( D_1 \) proceeds as follows.
   a) Pick \( b \leftarrow \{0, 1\} \), and compute
      \[ c^* = (u \| l2B(j_b)) \cdot G^* \oplus e, \]
      where \( u \leftarrow \mathbb{F}_2^{k-\ell} \) and \( e \leftarrow B(n, t) \).
   b) On input \((G^*, H, y_0, \ldots, y_{N-1}, c^*)\), simulate the NIZK\( \alpha \)K\( \Pi^* \) and output \( \Sigma^* = (c^*, \Pi^*) \).

We observe that if \( G^* \) is generated by ME.KeyGen(\( n, k, t \)) then the view of \( A \) in the interaction with \( D_1 \) is statistically close to its view in Experiment \( G_1^{(b)} \) with the challenger. On the other hand, if \( G^* \) is uniformly random, then \( A \)'s view is statistically close to its view in Experiment \( G_2^{(b)} \). Therefore, if \( A \) can guess whether it is interacting with the challenger in \( G_1^{(b)} \) or \( G_2^{(b)} \) with probability non-negligibly larger than 1/2, then \( D_1 \) can use \( A \)'s guess to solve the challenge instance \( G^* \) of the DMCe(\( n, k, t \)) problem, with the same probability.

**Experiment \( G_3^{(b)} \).** In Experiment \( G_2^{(b)} \) we have
\[ c^* = (u \| l2B(j_b)) \cdot G \oplus e = (u \cdot G \oplus e) \oplus l2B(j_b) \cdot G_2, \]
where
\[ u \leftarrow \mathbb{F}_2^{k-\ell}, \quad e \leftarrow B(n, t), \quad G_1 \in \mathbb{F}_2^{(k-\ell) \times n}, \quad \text{and } G_2 \in \mathbb{F}_2^{n \times n} \]
such that \( \frac{G_1}{G_2} = G \). Now, Experiment \( G_3^{(b)} \) modifies the generation of \( c^* \) by replacing the original one with
\[ c^* = v \oplus l2B(j_b) \cdot G_2, \]
where \( v \leftarrow \mathbb{F}_2^{k-\ell} \).

As shown in Lemma 7, Experiments \( G_2^{(b)} \) and \( G_3^{(b)} \) are computationally indistinguishable based on the assumed hardness of the DLPN(\( k-\ell, n, B(n, t) \)) problem.

**Lemma 7:** If \( A \) can distinguish Experiments \( G_2^{(b)} \) and \( G_3^{(b)} \) with probability non-negligibly larger than 1/2, then there exists an efficient distinguisher \( D_2 \) that can solve the DLPN(\( k-\ell, n, B(n, t) \)) problem with the same probability.

**Proof:** An instance of the DLPN(\( k-\ell, n, B(n, t) \)) problem is a pair \((B, v) \in \mathbb{F}_2^{(k-\ell) \times n} \times \mathbb{F}_2^{k-\ell} \), where \( B \) is uniformly random, and \( v \) is either uniformly random or of the form
\[ v = u \cdot B \oplus e, \quad \text{for } u \leftarrow \mathbb{F}_2^{k-\ell} \text{ and } e \leftarrow B(n, t). \]
The distinguisher \( D_2 \) receives a challenge instance \((B, v) \) and uses \( A \) to distinguish between the two. It interacts with \( A \) in the following manners.

1. **Setup.** Pick \( G_2 \leftarrow \mathbb{F}_2^{n \times k} \) and let \( G^* = \left[ \begin{array}{c} B \\ G_2 \end{array} \right] \). Generate \((H, y_0, \ldots, y_{N-1}) \) and \((gsk[0], \ldots, gsk[N-1]) \) as in the real scheme, and send \( A \) the pair
   \[ (gpk^* = (G^*, H, y_0, \ldots, y_{N-1}), gsk = (gsk[0], \ldots, gsk[N-1])). \]

2. **Challenge.** Upon receiving the challenge \((M^*, j_0, j_1)\), \( D_2 \) first picks \( b \leftarrow \{0, 1\} \) and lets
   \[ c^* = v \oplus l2B(j_b) \cdot G_2, \]
   where \( v \) comes from the challenge DLPN instance. It then simulates the NIZK\( \alpha \)K\( \Pi^* \), on input \((G^*, H, y_0, \ldots, y_{N-1}, c^*)\), and outputs \( \Sigma^* = (c^*, \Pi^*) \).

If \( D_2 \)'s input pair \((B, v) \) is of the form
\[ (B, v = u \cdot B \oplus e), \quad \text{where } u \leftarrow \mathbb{F}_2^{k-\ell} \text{ and } e \leftarrow B(n, t), \]
then the view of \( A \) in the interaction with \( D_2 \) is statistically close to its view in Experiment \( G_2^{(b)} \) with the challenger. On the other hand, if the pair \((B, v) \) is uniformly random, then \( A \)'s view is statistically close to its view in Experiment \( G_3^{(b)} \).

Therefore, if \( A \) can guess whether it is interacting with the challenger in \( G_2^{(b)} \) or \( G_3^{(b)} \) with probability non-negligibly larger than 1/2, then \( D_2 \) can use \( A \)'s guess to solve the challenge instance of the DLPN(\( k-\ell, B(n, t) \)) problem with the same probability.
Experiment $G_4$. This is a modification of Experiment $G_3^{(b)}$. The ciphertext $c^*$ is now set as $c^* = r \overset{\$}{\leftarrow} \mathbb{F}_2^n$. Clearly, the distributions of $c^*$ in Experiments $G_3^{(b)}$ and $G_4$ are identical. As a result, $G_4$ and $G_3^{(b)}$ are statistically indistinguishable. We note that $G_4$ no longer depends on the challenger’s bit $b$, and thus, $A$’s advantage in this experiment is 0.

The above discussion shows that Experiments $G_0^{(b)}, G_1^{(b)}, G_2^{(b)}, G_3^{(b)}, G_4$ are indistinguishable and that $\text{Adv}_A(G_4) = 0$. It then follows that the advantage of $A$ in attacking the CPA-anonymity of the scheme, i.e., in Experiment $G_0^{(b)}$, is negligible. The CPA-anonymity property is, thus, confirmed.

C. Traceability

Let $A$ be a PPT traceability adversary against our group signature scheme with success probability $\epsilon$. We construct a PPT algorithm $F$ that solves the SD($m, r, \omega$) problem with success probability polynomially related to $\epsilon$.

Algorithm $F$ receives a challenge SD($m, r, \omega$) instance, i.e., a uniformly random matrix-syndrome pair $(\hat{H}, \hat{y}) \in \mathbb{F}_2^{k \times m} \times \mathbb{F}_2^m$. The goal of $F$ is to find a vector $s \in \mathbb{B}$ such that $\hat{H} \cdot s^T = \hat{y}^T$. It then carries out the following steps:

1) Pick a guess $j^* \overset{\$}{\leftarrow} [0, N - 1]$ and set $y_j^* = \hat{y}$.
2) Set $H = \hat{H}$. For each $j \in [0, N - 1]$ such that $j \neq j^*$, sample $s_j \overset{\$}{\leftarrow} \mathbb{B}$ and set $y_j \in \mathbb{F}_2^m$ to be its syndrome, i.e., $y_j = H \cdot s_j$.
3) Run ME.KeyGen$(n, k)$ to obtain a key pair $(pk_{ME} = G \in \mathbb{F}_2^{k \times n} ; sk_{ME})$.
4) Send $gpk = (G, H, y_0, \ldots, y_N)$ and $gmsk = sk_{ME}$ to $A$.

Since the parameters $m, r, \omega$ were chosen such that $r \leq \log(\omega^n) - 2\lambda - O(1)$, Lemma 4 says that the distribution of the syndrome $y_j^*$, for all $j \neq j^*$, is statistically close to the uniform distribution over $\mathbb{F}_2^m$. In addition, the syndrome $y_{j^*} = \hat{y}$ is truly uniform over $\mathbb{F}_2^m$. It then follows that the distribution of $(y_0, \ldots, y_{N-1})$ is statistically close to that of the real scheme as noted in Remark 1. As a result, the distribution of $(gpk, gmsk)$ is statistically close to the distribution expected by $A$.

The forger $F$ then initializes a set $CU = \emptyset$ and handles the queries from $A$ according to the following procedure.

1) Queries to the random oracle $H$ are handled by consistently returning uniformly random values in $\{1, 2, 3\}^\ast$. Suppose that $A$ makes $Q_H$ queries, then for each $\eta \leq Q_H$, let $r_\eta$ denote the answer to the $\eta$-th query.

2) $O^{\text{Corrupt}}(j)$, for any $j \in [0, N - 1]$, depends on how $j$ and $j^*$ are related. If $j \neq j^*$, then $F$ sets $CU := CU \cup \{j\}$ and gives $s_j$ to $A$. If $j = j^*$, then $F$ aborts.

3) $O^{\text{Sign}}(j, M)$, for any $j \in [0, N - 1]$ and any message $M$, also depends on $j$ and $j^*$. If $j \neq j^*$, then $F$ honestly computes a signature, since it has the secret key $s_j$. If $j = j^*$, then $F$ returns a simulated signature $\Sigma^*$ computed as in Section IV-B. Please consult, specifically, Experiment $G_1^{(b)}$ in the proof of anonymity.

At some point, $A$ outputs a forged group signature $\Sigma^*$ on some message $M^*$, where

$$\Sigma^* = \left(\Sigma^*, (\text{CMT}(1), \ldots, \text{CMT}(\kappa)); \text{Ch}_1(1), \ldots, \text{Ch}_\kappa(1); \text{RSP}_1^{(1)}, \ldots, \text{RSP}_\kappa^{(1)}\right).$$

By the requirements of the traceability experiment, one has $\text{Verify}(gpk, M^*, \Sigma^*) = 1$ and, for all $j \in CU$, signatures of user $j$ on $M^*$ were never queried. Now $F$ uses $sk_{ME}$ to open $\Sigma^*$, and aborts if the opening algorithm does not output $j^*$. It can be checked that $F$ aborts with probability at most $(N - 1)/(N + 2)/(3)^\ast$. This is because the choice of $j^* \in [0, N - 1]$ is completely hidden from $A$’s view and $A$ can only violate the soundness of the argument system with probability at most $(2/3)^\ast$. Thus, with probability at least $1/(N - (2/3)^\ast$.

$$\text{Verify}(gpk, M^*, \Sigma^*) = 1 \land \text{Open}(sk_{ME}, M^*, \Sigma^*) = j^*.$$ (14)

Suppose that (14) holds. Algorithm $F$ then exploits the forgery as follows. Denote by $\Delta$ the tuple $(M^*; \text{CMT}(1), \ldots, \text{CMT}(\kappa); G, H, y_0, \ldots, y_{N-1}, c^*)$.

Observe that if $A$ has never queried the random oracle $H$ on input $\Delta$, then $\text{Pr}[(\text{Ch}_1(1), \ldots, \text{Ch}_\kappa(1)) = H(\Delta)] \leq 3^{-\kappa}$. Thus, with probability at least $\epsilon - 3^{-\kappa}$, there exists certain $\eta^* \leq Q_H$ such that $\Delta$ was the input of the $\eta^*$-th query. Next, $F$ picks $\eta^*$ as the target forking point and replays $A$ many times with the same random tape and input as in the original run. In each rerun, for the first $\eta^* - 1$ queries, $A$ is given the same answers $r_1, \ldots, r_{\eta^* - 1}$ as in the initial run. From the $\eta^*$-th query onwards, however, $F$ replies with fresh random values $r_{\eta^*}, \ldots, r_{\eta^*} \overset{\$}{\leftarrow} \{1, 2, 3\}^\ast$. The Improved Forking Lemma of Pointcheval and Vaudenay [66 Lemma 7] implies that, with probability larger than 1/2 and within less than $32 \cdot Q_H/(\epsilon - 3^{-\kappa})$ executions of $A$, algorithm $F$ can obtain a 3-fork involving the tuple $\Delta$. Now, let the answers of $F$ with respect to the 3-fork branches be

$$r_1, \eta^* = (\text{Ch}_1(1), \ldots, \text{Ch}_\kappa(1));$$
$$r_2, \eta^* = (\text{Ch}_2(1), \ldots, \text{Ch}_\kappa(1));$$
$$r_3, \eta^* = (\text{Ch}_3(1), \ldots, \text{Ch}_\kappa(1)).$$

Then, by a simple calculation, one has

$$\text{Pr}[\exists i \in \{1, \ldots, \kappa\} : \{\text{Ch}_1(i), \text{Ch}_2(i), \text{Ch}_3(i)\} = \{1, 2, 3\}] = 1 - (7/9)^\kappa.$$ (14)

Conditioned on the existence of such index $i$, one parses the three forgeries corresponding to the fork branches to obtain $(\text{RSP}_1^{(i)}, \text{RSP}_2^{(i)}, \text{RSP}_3^{(i)})$. They turn out to be three valid responses with respect to 3 different challenges for the same commitment $\text{CMT}(i)$. Then, by using the knowledge extractor of the underlying interactive argument system (see Lemma 4), one can efficiently extract a tuple

$$(j^*, s', u', e') \in [0, N - 1] \times \mathbb{F}_2^m \times \mathbb{F}_2^{k-\ell} \times \mathbb{F}_2^n$$
such that
\[ \mathbf{H} \cdot \mathbf{s}'^T = \mathbf{y}'_j^T, \quad \mathbf{s}' \in \mathcal{B}(m, \omega) \]

Since the given group signature scheme is correct, the equation

\[ (u' \| 12B(j')) \cdot \mathbf{G} \oplus e' = c^* \]

implies that
\[ \text{Open}(\text{sk}_\text{ME}, M^*; \Sigma^*) = j'. \]

On the other hand, we have
\[ \text{Open}(\text{sk}_\text{ME}, M^*; \Sigma^*) = j^* \]

which leads to \( j' = j^* \). Therefore, it holds that
\[ \mathbf{H} \cdot \mathbf{s}'^T = \mathbf{H} \cdot \tilde{\mathbf{s}}^T = \mathbf{y}'_j = \tilde{\mathbf{y}}' \] and \( \mathbf{s}' \in \mathcal{B}(m, \omega) \).

In other words, \( \mathbf{s}' \) is a valid solution to the challenge \( SD(m, r, \omega) \) instance \( (\mathbf{H}, \tilde{\mathbf{y}}') \).

Finally, the above analysis shows that, if \( A \) has success probability \( c \) and running time \( T \) in attacking the traceability of our group signature scheme, then \( F \) has success probability at least \( 1/2 \left( 1/N - (2/3)^s \right) \left( 1 - (7/9)^s \right) \) and running time at most \( 32 \cdot T \cdot Q_S/t + \text{poly}(\lambda, N) \). This concludes the proof of the traceability property.

V. ACHIEVING CCA-ANONYMITY

In this section, we propose and analyse a code-based group signature that achieves the strong notion of CCA- anonymity. The scheme is an extension of the CPA-anonymous scheme described in Section IV-A. To achieve CCA-security for the underlying encryption layer via the Naor-Yung transformation [51], the binary representation of the signer’s index \( j \) is now verifiably encrypted twice under two different randomized McEliece public keys \( \text{pk}_\text{ME}^{(1)} \) and \( \text{pk}_\text{ME}^{(2)} \). This enables CCA-anonymity for the resulting group signature scheme. In describing the scheme, the focus is on presenting the modifications that we must make with respect to the earlier scheme from Section IV-A.

A. Description of the Scheme

We start with the four algorithms that constitute the scheme.

1) KeyGen(1^λ, 1^n): The algorithm proceeds as the key generation algorithm of Section IV-A with the following alteration. \( \text{ME.KeyGen}(n, k, t) \) is run twice, producing two key pairs
\[ (\text{pk}_\text{ME}^{(1)} = \mathbf{G}^{(1)}; \text{sk}_\text{ME}^{(1)}) \] and
\[ (\text{pk}_\text{ME}^{(2)} = \mathbf{G}^{(2)}; \text{sk}_\text{ME}^{(2)}) \]

for the randomized McEliece encryption. Then \( \mathbf{G}^{(1)} \) and \( \mathbf{G}^{(2)} \) are included in the group public key \( \text{gpk} \), the opening secret key \( \text{gmsk} \) is defined to be \( \text{sk}_\text{ME}^{(1)} \), while \( \text{sk}_\text{ME}^{(2)} \) is discarded.

2) Sign(\text{gsk}[j], M): The binary representation 12B(j) \( j \in \mathbb{F}_2^d \) of the user’s index \( j \) is now encrypted twice, under the keys \( \mathbf{G}^{(1)} \) and \( \mathbf{G}^{(2)} \). The resulting ciphertexts \( e^{(1)} \) and \( e^{(2)} \) have the form
\[ e^{(1)} = (u^{(1)} \| 12B(j)) \cdot \mathbf{G}^{(1)} \oplus e^{(1)} \in \mathbb{F}_2^d \]
\[ e^{(2)} = (u^{(2)} \| 12B(j)) \cdot \mathbf{G}^{(2)} \oplus e^{(2)} \in \mathbb{F}_2^d \]

where \( u^{(1)}, u^{(2)} \subseteq \mathbb{F}_2^{k-\ell} \) and \( e^{(1)}, e^{(2)} \subseteq \mathbb{B}(n, t) \).

The zero-knowledge protocol of the scheme from Section IV-A is then developed to enable the prover, possessing witness \( (j, s, u^{(1)}, u^{(2)}, e^{(1)}, e^{(2)}) \), to convince the verifier, with public input \( (\mathbf{G}^{(1)}, \mathbf{G}^{(2)}, \mathbf{H}, u_0, ..., u_{n-1}, c^{(1)}, c^{(2)}) \), that
\[ \mathbf{H} \cdot \mathbf{s}'^T = y_{j}^T, \quad s \in \mathcal{B}(m, \omega), \]
\[ e^{(1)} \in \mathcal{B}(n, t), \quad e^{(2)} \in \mathcal{B}(n, t), \]
\[ (u^{(1)} \| 12B(j)) \cdot \mathbf{G}^{(1)} \oplus e^{(1)} = c^{(1)}, \]
\[ (u^{(2)} \| 12B(j)) \cdot \mathbf{G}^{(2)} \oplus e^{(2)} = c^{(2)}. \quad (15) \]

The zero-knowledge protocol of the scheme from Section III-B can be employed for the above zero-knowledge protocol.

Let \( \Pi \) be the NIzkAOK obtained by repeating the protocol \( \kappa = \omega \cdot \log \lambda \) times and making it non-interactive via the Fiat-Shamir heuristic. The group signature is set to be \( \Sigma = (c^{(1)}, c^{(2)}; \Pi) \), where
\[ \Pi = (\text{CMT}^{(1)}, ..., \text{CMT}^{(k)}), \]
\[ (\text{Ch}^{(1)}, ..., \text{Ch}^{(k)}); \text{RSP}^{(1)}, ..., \text{RSP}^{(k)} \quad (16) \]

and \( (\text{Ch}^{(1)}, ..., \text{Ch}^{(k)}) \in \{1, 2, 3\}^k \) is given by
\[ \mathcal{H}(\mathbf{M}; \text{CMT}^{(1)}, ..., \text{CMT}^{(k)}; \text{gpk}, c^{(1)}, c^{(2)}). \]

3) Verify(\text{gpk}, M, \Sigma): This algorithm proceeds as the verification algorithm of the scheme from Section IV-A with \( (c^{(1)}, c^{(2)}) \) taking the place of \( c \).

4) Open(\text{gmsk}, M, \Sigma): Parse \( \Sigma \) as \( (c^{(1)}, c^{(2)}; \Pi) \) and run \( \text{ME.Dec}(\text{gmsk}, c^{(1)}) \) to decrypt \( c^{(1)} \). If decryption fails, then return \( \perp \). If decryption outputs \( g \in \mathbb{F}_2 \), then return \( j = \text{B2I}(g) \in [0, N - 1] \).

The efficiency, correctness, and security aspects of the above group signature scheme are summarized in the following theorem.

Theorem 8: The given group signature scheme is correct. The public key has size \( 2nk + (m + N)r \) bits while the signatures have bit-size bounded above by
\[ ((N + 3 \log N) + m(\log m + 1) + 2n(\log n + 1 + 2k + 5\lambda) \kappa + n. \]

In the random oracle model we can make two further assertions. First, if the Decisional McEliece problem DMcE(n, k, t) and the Decisional Learning Parity with fixed-weight Noise problem DLPN(k – \ell, n, B(n, t)) are hard, and if the underlying NIzkAOK system is simulation-sound, then the scheme is CCA-anonymous. Second, if the Syndrome Decoding problem \( \text{SD}(m, r, \omega) \) is hard, then the scheme is traceable.

Compared with the basic scheme in Section IV the present scheme introduces one more McEliece encrypting matrix of size \( nk \) bits in the group public key, one more \( n \)-bit ciphertext and its supporting ZK sub-argument of well-formedness contained in \( \Pi \) in the group signature. Overall, the upgrade
from CPA-anonymity to CCA-anonymity incurs only a small and reasonable overhead in terms of efficiency. Since the correctness and traceability analyses of the scheme are almost identical to those of the basis scheme in Section IV, the details are omitted here. In the next subsection, we will prove the CCA-anonymity property, which is the distinguished feature that we aim to accomplish.

B. A Scheme Achieving CCA-Anonymity

Let $A$ be any PPT adversary attacking the CCA-anonymity of the scheme with advantage $\epsilon$. We will prove that $\epsilon = \text{negl}(\lambda)$ based on the ZK property and simulation-soundness of the underlying argument system. We keep the assumed hardness of the $\text{DMcE}(n, k, t)$ and the $\text{DLPN}(k - \ell, n, B(n, t))$ problems. Specifically, we consider the following sequence of hybrid experiments $G_0^{(b)}$, $G_1^{(b)}$, \ldots, $G_{11}^{(b)}$, where $b$ is the bit chosen by the challenger when generating the challenge signature.

**Experiment $G_0^{(b)}$.** This is the real CCA-anonymity experiment. The challenger runs $\text{KeyGen}(1^\lambda, 1^N)$ to obtain

$$(gpk = (G_1, G_2, H, y_0, \ldots, y_{N-1}), gmsk = \text{sk}_{\text{ME}}(1), \text{gsk} = (\text{gsk}[0], \ldots, \text{gsk}[N-1])),$$

and then gives $gpk$ and $\{\text{gsk}[j]\}_{j\in[0,N-1]}$ to $A$. Queries to the opening oracle are answered using the secret key $\text{sk}_{\text{ME}}(1)$. In the challenge phase, $A$ outputs a message $M^*$ together with two indices $j_0, j_1 \in [0, N-1]$. The challenger sends back a challenge signature

$$\Sigma^* = (c^{(1)}^*, c^{(2)}^*, \Pi^*) \leftarrow \text{Sign}(gpk, \text{gsk}[j_0]).$$

The adversary outputs $b$ with probability $1/2 + \epsilon$.

**Experiment $G_1^{(b)}$.** The only difference between this experiment and Experiment $G_0^{(b)}$ is that the challenger, when running $\text{KeyGen}(1^\lambda, 1^N)$, retains the second decryption key $\text{sk}_{\text{ME}}(2)$ instead of discarding it. The views of $A$ in the two experiments are identical.

**Experiment $G_2^{(b)}$.** This experiment is like Experiment $G_0^{(b)}$ with one modification in the signature opening oracle. Instead of using $\text{sk}_{\text{ME}}(1)$ to open signatures, the challenger uses $\text{sk}_{\text{ME}}(2)$. It is easy to see that $A$’s view will be the same as in Experiment $G_2^{(b)}$ until an event $F_2$ when $A$ queries the opening of a signature $\Sigma = (c^{(1)}, c^{(2)}, \Pi)$ for which $c^{(1)}$ and $c^{(2)}$ encrypt distinct elements of $\mathbb{F}_2^n$. Since such an event $F_2$ could break the soundness of the zero-knowledge protocol used to generate $\Pi$, it could happen only with negligible probability. Therefore, the probability that $A$ outputs $b$ in this experiment is negligibly close to $1/2 + \epsilon$.

**Experiment $G_3^{(b)}$.** This experiment is identical to Experiment $G_2^{(b)}$, except on one modification. Instead of faithfully computing the NIZKAoK $\Pi^*$ using witness $(j, s, u^{(1)}, u^{(2)}, e^{(1)}, e^{(2)})$, the challenger simulates it by running the simulator of the underlying zero-knowledge protocol and programming the random oracle $H$. Note that $\Pi^*$ is a simulated argument for a true statement, since $c^{(1)}^*$ and $c^{(2)}^*$ are honestly computed. Thanks to the statistical zero-knowledge property of the underlying protocol, Experiment $G_3^{(b)}$ is statistically close to Experiment $G_2^{(b)}$.

**Experiment $G_4^{(b)}$.** This experiment is similar to Experiment $G_2^{(b)}$ in the proof of CPA-anonymity in Section IV-B. The only modification, with respect to the encrypting key $G^{(1)}$, is that instead of generating it using $\text{ME.KeyGen}(n, k, t)$, we sample it uniformly at random over $\mathbb{F}_2^n$. By the assumed hardness of the $\text{DMcE}(n, k, t)$ problem, this experiment is computationally indistinguishable from the previous experiment.

**Experiment $G_5^{(b)}$.** This experiment is similar to Experiment $G_3^{(b)}$ in the proof of CPA-anonymity in Section IV-B. Instead of computing $c^{(1)}^*$ as

$$c^{(1)}^* = (u^{(1)} \parallel I2B(j_0)) \cdot G^{(1)} + e^{(1)} = (u^{(1)} \cdot G^{(1)} + e^{(1)}) \oplus I2B(j_0) \cdot G^{(2)},$$

we let

$$c^{(1)}^* = \psi + I2B(j_0) \cdot G^{(2)}, \text{ where } \psi \leftarrow \mathbb{F}_2^n.$$

The simulated NIZKAoK $\Pi^*$ now corresponds to a false statement, since $c^{(1)}^*$ is not a well-formed ciphertext. Nevertheless, assuming the hardness of the $\text{DLPN}(k - \ell, n, B(n, t))$ problem, in the challenge phase the adversary $A$ can only observe the modification of $c^{(1)}^*$ with probability at most negligible in $\lambda$. The view of $A$ is thus computationally close to that in Experiment $G_4^{(b)}$ above until an event $F_5$ which could happen after the challenge phase when $A$ queries the opening of a signature $\Sigma = (c^{(1)}, c^{(2)}, \Pi)$ for which $c^{(1)}$ and $c^{(2)}$ encrypt distinct elements of $\mathbb{F}_2^n$. Since such an event $F_5$ could break the simulation-soundness of the underlying NIZKAoK, it could happen only with negligible probability. Therefore, the success probability of $A$ in this experiment is negligibly close to that in Experiment $G_5^{(b)}$.

**Experiment $G_6^{(b)}$.** This experiment modifies Experiment $G_5^{(b)}$ slightly. The ciphertext $c^{(1)}^*$ is now $c^{(1)}^* = 2^k \cdot \psi \cdot \mathbb{F}_2^n$. Clearly, the distributions of $c^{(1)}^*$ in $G_6^{(b)}$ and $G_5^{(b)}$ are identical. Hence, the two experiments are statistically indistinguishable.

**Experiment $G_7^{(b)}$.** This experiment switches the encrypting key $G^{(1)}$ back to an honest key generated by $\text{ME.KeyGen}(n, k, t)$, and stores the corresponding decryption key $\text{sk}_{\text{ME}}(1)$. By the assumed hardness of the $\text{DMcE}(n, k, t)$ problem, this experiment is computationally indistinguishable from Experiment $G_6^{(b)}$.

**Experiment $G_8^{(b)}$.** In this experiment, we use $\text{sk}_{\text{ME}}(1)$, instead of $\text{sk}_{\text{ME}}(2)$, to answer signature opening queries. The view of $A$ is identical to that in Experiment $G_7^{(b)}$ above until an event $F_8$ when $A$ queries the opening of a signature $\Sigma = (c^{(1)}, c^{(2)}, \Pi)$ for which $c^{(1)}$ and $c^{(2)}$ encrypt distinct elements of $\mathbb{F}_2^n$. Since such an event $F_8$ could break the simulation-soundness of the underlying NIZKAoK, it could happen only with negligible probability.

**Experiment $G_9^{(b)}$.** This experiment is similar to Experiment $G_8^{(b)}$ above. We replace the randomized McEliece encrypting
key $G^{(2)}$ by a uniformly random matrix in $\mathbb{F}_2^{k \times n}$. By the assumed hardness of the DMcE$(n, k, t)$ problem, this experiment is computationally indistinguishable from Experiment $G_8^{(b)}$.

**Experiment $G_6^{(b)}$.** This experiment is akin to Experiment $G_5^{(b)}$. The second ciphertext $c^{(2),*}$ is now computed as

$$c^{(2),*} = \nu^{(2)} \oplus 12B(j_h) \cdot G^{(2)}_2,$$

where $\nu^{(2)} \in \mathbb{F}_2^{n}$.

Assuming the hardness of the DLPN$(k - \ell, n, B(n, t))$ problem, this experiment is computationally indistinguishable from Experiment $G_9^{(b)}$.

**Experiment $G_{11}$.** This experiment resembles Experiment $G_6^{(b)}$. The second ciphertext is now $c^{(2),*} = r^{(2)} \cdot x \in \mathbb{F}_2^{n}$.

Clearly, the distributions of $c^{(2),*}$ in $G^{(b)}_6$ and $G_{11}$ are identical. Hence, the two experiments are statistically indistinguishable. Moreover, since $G_{11}$ no longer depends on the challenger’s bit $b$, the advantage of $A$ is 0 here.

The above discussion establishes that Experiments $G^{(b)}_0$, $G^{(b)}_1$, ..., $G^{(b)}_{10}$, $G_{11}$ are indistinguishable and that $A$ has no advantage in $G_{11}$. It then follows that the advantage of $A$ in attacking the CCA-anonymity of the scheme, i.e., in Experiment $G^{(b)}_6$, is negligible. This concludes the justification for the CCA-anonymity property.

## VI. Implementation Results

This section presents basic implementation results of our proposed group signature schemes to certify their feasibility.

### A. Test Environment

The testing platform was a modern PC with a 3.4 GHz Intel Core i5 CPU and 32 GB of RAM. We employed the NTL [67] and gf2x [68] libraries for efficient polynomial operations over fields of characteristic 2. The Paterson decoding algorithm [69] was used on the binary Goppa codes to implement the McEliece encryption. We employed SHA-3 with various output sizes to realize several hash functions.

To achieve 80-bit security, we decided on the following parameters. The McEliece parameters were set to $(n, k, t) = (2^{11}, 1096, 32)$, as in [70]. The parameters for Syndrome Decoding were set to $(m, r, \omega) = (2756, 550, 121)$ so that the distribution of $y_0, \ldots, y_{N-1}$ is $2^{-80}$-close to the uniform distribution over $\mathbb{F}_2^n$, by Lemma 1 and that the SD$(m, r, \omega)$ problem is intractable with respect to the best known attacks. In particular, these parameters ensure the following work factor evaluations. First, the Information Set Decoding algorithm proposed in [43] has work factor more than $2^{80}$. For an evaluation formula, one can also refer to [71] Slide 3. Second, the birthday attacks presented in [42] have work factors more than $2^{80}$. The number of protocol repetitions $\kappa$ was set to 140 to obtain soundness $1 - 2^{-80}$.

### B. Experimental Results

Table 1 shows the implementation results of our CPA-anonymous group signature scheme, together with its public key and signature sizes, with respect to various numbers of group users and different message sizes. To reduce the signature size, in the underlying zero-knowledge protocol, we sent a random seed instead of permutations when $Ch = 2$. Similarly, we sent a random seed instead of the whole response RSP when $Ch = 3$. Using this technique, the average signature sizes were reduced to about 159 KB for 4,096 = $2^{12}$ users and to 876 KB for 65,536 = $2^{16}$ users, respectively. Our public key and signature sizes are linear in the number of group users $N$, but it does not come to the fore while $N$ is less than $2^{12}$ due to the respective sizes of $G$ and $H$.

Our implementation took 0.282 and 0.186 seconds for a 1 B message and 5.591 and 5.497 seconds for a 1 GB message, respectively, to sign a message and to verify a generated signature for a group of 65,536 users. In our experiments, it took about 5.30 seconds to hash a 1 GB message, leading to the differences of signing and verifying times between a 1 B and a 1 GB messages. One may naturally expect that running times should increase as $N$ grows. But, as recorded in Table 1, the increases were negligible and on occasions, the running time even decreased slightly as $N$ grew up to $2^{12}$. This could also be due to the effect that the time required to perform other basic operations with parameters $G$ and $H$ had on the overall running time.

Table 1 contains the implementation results of our CCA-anonymous group signature scheme, along with public key and average signature sizes for various number of group users and different message sizes. The public key size of our CCA-anonymous scheme was 434 KB larger than that of our CPA-anonymous version because of the additionally required matrix $G^{(2)}$. The average signature size was also about 46 KB larger since the response RSP additionally included $ve^{(2)}$, $we^{(2)}$ when $Ch = 1$ and $zu^{(2)}$, $ze^{(2)}$ when $Ch = 2$. We remark that there was no additional element to be sent for $Ch = 3$ since we just sent a random seed instead of the whole response, as in the implementation of our CPA-anonymous scheme. The results in Table 1 show that the CCA-anonymous version requires only a small overhead for key generation, signing, and verification. For example, the key generation algorithm took about 5 seconds more, which corresponds to the key generation time for the McEliece encryption. When the number of group users was less than $2^{20}$, it also took about 0.020 seconds and 0.015 seconds more to generate a signature and to verify it, respectively. The overheads for signing were increased slightly once the number of group users reached $2^{24}$, but they account for about 2.28% and 2.73% of the total signing times for 1 B and 1 GB messages, respectively.

In conclusion, to our best knowledge, the implementation results presented here are the first ones for group signatures from quantum-resistant assumptions. We have thus demonstrated that our schemes, while not yet truly practical, are bringing this class of group signatures closer to practice.

## VII. Conclusion

We put forward two provably secure code-based group signature schemes in the random oracle model. The first scheme satisfies the CPA-anonymity and traceability requirements for group signatures under the assumed hardness of three well-known problems in code-based cryptography. These are the

McEliece problem, the Learning Parity with Noise problem, and a variant of the Syndrome Decoding problem. We extend the basic scheme to achieve CCA-aniomy by exploiting the Naor-Yung transformation. The feasibility of the proposed schemes is backed by implementation results.

The work we presented here inaugurates a foundational step in code-based group signatures. The natural continuation is to work towards either one of the following goals: constructing practically efficient schemes whose signature sizes are sub-linear in the number of group users and obtaining provably secure schemes in either the standard model or in the quantum random oracle model discussed in, e.g., [72].

ACKNOWLEDGEMENTS

We thank Jean-Pierre Tillich, Philippe Gaborit, Ayoub Otmani, Nicolas Sendrier, and Nico Döttling for helpful comments and discussions.

Martianus Frederic Ezerman grew up in East Java Indonesia. He received the B.A. degree in philosophy and the B.Sc. degree in mathematics in 2005 and the M.Sc. degree in mathematics in 2007, all from Ateneo de Manila University, Philippines. In 2011 he obtained the Ph.D. degree in mathematics from Nanyang Technological University (NTU), Singapore. After research fellowships at Laboratoire d’Information Quantique, Université Libre de Bruxelles, Belgium and at the Centre for Quantum Technologies (CQT), National University of Singapore, he returned in March 2014 to NTU where he is currently a Senior Research Fellow. He is interested in coding theory, cryptography, and quantum information processing.

Hyung Tae Lee received the B.Sc., M.Sc., and Ph.D. degrees in mathematics from Seoul National University, Republic of Korea, in 2006, 2008, and 2013, respectively. He is currently an assistant professor with the Division of Computer Science and Engineering, College of Engineering, Jeonbuk National University, Republic of Korea. Prior to that, he was a research fellow with Nanyang Technological University, Singapore. His research interests include computational number theory, cryptography, and information security.

San Ling received the B.A. degree in mathematics from the University of Cambridge and the Ph.D. degree in mathematics from the University of California, Berkeley. He is currently President’s Chair in Mathematical Sciences, at the Division of Mathematical Sciences, School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, which he joined in April 2005. Prior to that, he was with the Department of Mathematics, National University of Singapore. His research fields include: arithmetic of modular curves and application of number theory to combinatorial designs, coding theory, cryptography and sequences.
